certain clinical settings VUDS is the test of choice (see later). In addition to the necessary urodynamic hardware and software, a fluoroscopy unit and room of adequate size are required. Obviously, this is not practical or necessary in every setting. VUD studies also require a greater time commitment on the part of the clinician to ensure accurate data collection. Thus VUDS is ideally performed in centers with a specific interest in complex storage and voiding dysfunction. For specific recommendations regarding UDS equipment performance, the reader is referred to the recently published ICS document on this subject (Gammie et al, 2014).

Signal Transmission and Transducers

Transducers are the hardware that allows pressure in the patient to be measured and measurements transferred to the UDS system. External strain gauge transducers located between the patient and the urodynamic machine have been popular for years. Pressurized tubing (to avoid damping or dissipating the pressure) extends from the pressure transducer to the catheters placed in the patient. An electronic cable or wireless transmission brings the signal from the transducer to the urodynamic machine. Traditionally a water-filled system was used in which the entire system from transducer to patient is filled with water. Because this system depends on the transmission of pressure through fluid (water), it is crucial that there are no air bubbles in the transducer or tubing. The pressurized tubing transmission lines should be lucent to allow for easy recognition of air in the line. The transducers are usually set at the level of the patient's bladder (symphysis pubis) at the start of the study. This is important, because if the patient changes position during the test (e.g., standing to sitting), the height of the transducer can be adjusted so that it remains at the level of the bladder.

More recently, **air-charged catheters** (T-Doc, Wenonah, NJ) have become popular for pressure measurement. Air-charged catheters

use a miniature air-filled balloon placed circumferentially around a polyethylene catheter. External forces on the balloon of the catheter are transmitted to the air-filled catheter lumen and communicated to an external semiconductor transducer. The technology of the balloon system allows circumferential measurement readings. The catheters are disposable and for single use. Air-charged catheters have several practical advantages over fluid-filled pressure lines because there is no fluid connection between the patient and the urodynamic equipment, just air. This means there is no hydrostatic pressure effect to account for, so there is no need to position anything at the level of the symphysis pubis and no need to flush the system through to exclude air (essential when using a fluid-filled system). Also, there are no artifactual fluctuations in pressure produced when the patient moves. It must be remembered that **many UDS nomograms and other standards of measurement were determined using fluid-filled systems. There is comparative evidence for the use of air-charged catheters to measure urethral pressure and Valsalva leak point pressure**, with one study showing comparable performance between air-charged and microtip catheters (Pollak et al, 2004) and one study concluding that they cannot be used interchangeably, because air-charged catheters showed systematically higher readings (Zehnder et al, 2008).

Cooper and colleagues (2011), in an experimental model, showed that **air-charged and water-filled catheters respond to pressure changes in dramatically different ways**. Water-filled catheters acted as an underdamped system, resonating at 10.13 ± 1.03 Hz and attenuating signals at frequencies higher than 19 Hz. They demonstrated significant motion and hydrostatic artifacts. Air-charged catheters acted as an overdamped system and attenuated signals at frequencies higher than 3.02 ± 0.13 Hz. They demonstrated significantly less motion and hydrostatic artifacts than water-filled catheters. The authors point out that most urodynamic signals occur below 3 Hz, and thus air-charged systems could be beneficial

Figure 73-2. Cystometrography (CMG) measures the pressure in the bladder as the bladder fills over time. Standard fill rates in adults are 30 to 100 cm H₂O per minute. Adding intra-abdominal pressure monitoring gives a better representation of the true detrusor pressure (Pdet). A, Single-channel CMG in which only the total vesical pressure (Pves) is measured. Note the multiple spikes and rises in pressure. Without having simultaneous monitoring of intra-abdominal pressure (Pabd), it is impossible to know if these pressure spikes are due to a rise in detrusor or abdominal pressure. B, The same tracing with Pabd monitoring added (multichannel urodynamics). This allows for the determination of (subtracted) Pdet. Here it can be clearly seen that changes in Pves were due to the changes in Pabd (movement, coughing, etc.). The Pdet curve is noted to be flat and without any rises in pressure. (From Nitti VW. Cystometry and abdominal pressure monitoring. In: Nitti VW, editor. *Practical urodynamics*. Philadelphia: Saunders; 1998. p. 38–51.)

because most of the higher frequency noise is damped. However, urodynamic signals can have frequency components greater than 3 Hz, particularly when using rapidly changing signals, such as coughs. The authors concluded that “knowledge of the characteristics of the pressure-measuring system is essential to finding the best match for a specific application.” The conclusions of the 5th International Consultation on Incontinence (Rosier et al, 2013) are that air-charged catheters may provide an acceptable alternative for measuring the closure pressure of the female urethra, but there have been no studies to show that air-charged catheters provide a superior alternative to fluid-filled lines for measuring intravesical and intra-abdominal pressure. Thus it is recommended that investigators planning to use air-charged catheters for intravesical and intra-abdominal pressure monitoring check for themselves that they have an equivalent performance to their current system for measuring pressure (Rosier et al, 2013).

Finally, a microtip or fiberoptic system can be used to process pressure transmission. In this system the transducer is contained within the catheter. This in turn is connected directly into the urodynamic machine via a cable. These catheters are quite expensive and reusable and must be sterilized before each use.

Uroflowmeters

Urine flow rate, or uroflow, can be determined by a number of different types of devices or uroflowmeters. Modern uroflowmeters use weight, electrical capacitance, or a rotating disc to determine urinary flow rates. The two most common techniques today are the weight transducer or load cell method and the rotating disc method. With the load cell the voided weight is measured and then differentiated with respect to time to determine the flow rate. In the rotating disc method the urine stream is directed onto a rotating disc and the power necessary to keep a disc rotating at a constant rate is mea-

sured. This power is proportional to the flow rate. The electronic dipstick flowmeter measures the electrical capacitance of a dipstick mounted in a collecting chamber. The output of the signal is proportional to the accumulated volume, and the volumetric flow rate is determined by differentiation. Each of these methods has advantages and disadvantages. The weight transducer method is simple, reliable, and accurate, regardless of the site of stream impact, but requires that the density of urine must be set. The rotating disc method is also reliable and accurate and provides a direct measurement without need for differentiation of volume with respect to time. Electronic flowmeters provide a range of electronically read flow parameters with graphic depiction of the uroflow and have sufficient precision for clinical use with error rates of 1% to 8% in voided volume and 4% to 15% in flow rate (Susset, 1983). Variations in specific gravity of the fluid voided (infusant when doing UDS studies) can affect the calculated flow rate. Most systems allow for calibrations for various fluids such as radiographic contrast agent.

Electromyography

Muscle depolarization must be detected by an electrode placed in or near the muscle. Several different methods are available, including surface electrodes, needle electrodes (which are the two most common methods), and anal plug or urethral catheter-mounted electrodes (O'Donnell, 1998). Surface electrodes are self-adhesive skin patch electrodes that are applied over the skin of the anal sphincter (Barrett, 1980). Except in some neurologic diseases, external anal sphincter EMG will be the same as the external urethral sphincter EMG. Surface electrodes have a significant advantage compared with the needle electrode regarding patient convenience and comfort. However, the surface electrodes provide an inferior signal source and must be precisely placed to provide an adequate signal source. Most clinicians think the concentric needle electrode is the superior technique for obtaining a signal source of EMG activity of the striated external sphincter muscles. Compared with the surface electrode, placement of the needle electrode has the disadvantage of being uncomfortable for the patient, especially if more than one attempt at placement of the electrode is required to obtain an adequate signal. Also, the needle electrode is easily dislodged and may require replacement during the study. Patients typically have a low tolerance for replacement of the needle electrode during urodynamic studies (Brucker et al, 2012). The performance of EMG and the selection of the type of electrode to be used depend on the UDS question to be answered.

KEY POINTS: URODYNAMICS PERFORMANCE AND INTERPRETATION

- There should be a clearly defined reason to perform a UDS study. The intention should be that the information that may be obtained could be used to guide patient treatment.
- UDS is only one part of the comprehensive evaluation of symptoms and LUT function, and the main goal of UDS is to reproduce patient symptoms, when present, and determine the cause of the symptoms by urodynamic measurements or observations.
- UDS studies should be interpreted in the context of patient history, including symptoms, concomitant diseases/conditions, and other information, such as PVR volumes and frequency volume charts (voiding and intake diaries) when clinically applicable.
- Proper urodynamic practices and appropriate terminology should be used when possible.
- Well-trained, attentive, and supportive staff involved with the UDS study cannot be overemphasized. Patients should be properly prepared and told why the test is being done, how the results may affect treatment, and what to expect during the actual UDS test.

THE URODYNAMIC STUDY: ANALYSIS AND INTERPRETATION

We have found it useful to divide the UDS test into filling/storage and voiding phases. This allows for ease of classification of voiding dysfunction according to the functional classification system mentioned previously. The filling/storage phase consists primarily of CMG and provocative testing (e.g., measurement of abdominal leak point pressure [ALPP]), and urethral pressure measurement during storage. The voiding phase evaluates bladder contractility, bladder outlet resistance, and sphincter coordination by pressure-flow analysis and EMG.

FILLING AND STORAGE PHASE

The CMG assesses the bladder's response to filling. It can measure filling pressure, sensation, involuntary contractions, compliance, and capacity. Sensation is the part of CMG that is truly subjective and therefore requires an alert and attentive patient and clinician. Several subjective parameters can be recorded during filling that are recognized by the ICS (see Box 73-2). Categorizing LUT sensation during bladder filling (e.g., urinary urgency or early filling sensation) is now thought to be more clinically important than previously thought. Some treatments are thought to have a specific influence on sensation (de Wachter et al, 2011; Heeringa et al, 2011).

Normal Filling and Storage

Normally, the bladder should store urine at a low pressure and not contract involuntarily. Once capacity is reached or voluntary voiding is desired, intravesical pressure will increase (voluntary detrusor contraction). In actuality this is preceded by a relaxation of the external sphincter. A normalized adult CMG image is shown in Figure 73-3. Normally Pdet should remain near zero during the entire filling cycle until voluntary voiding is initiated. That means baseline pressure stays constant (and low) and there are no involuntary contractions.

As mentioned previously, the simultaneous measurement of Pabd, usually by a rectal or vaginal catheter, and Pves during UDS provides a means of calculating the true Pdet. The ability to calculate subtracted Pdet allows distinguishing between a true rise in Pdet (via either a contraction or loss of compliance) and the

effect of increased Pabd (e.g., straining, Valsalva). This is especially important when rises in Pdet are small or when they are accompanied by changes in Pabd.

Abnormalities of Bladder Filling: Detrusor Overactivity and Impaired Compliance

During filling, involuntary detrusor contractions (IDCs) can occur. These are often associated with urgency and even urgency incontinence. DO is a urodynamic observation characterized by IDCs during the filling phase that may be spontaneous or provoked (Fig. 73-4). DO may be further characterized as neurogenic DO when it is associated with a relevant neurologic condition (e.g., spinal cord injury, multiple sclerosis) or idiopathic DO when there is no defined cause (non-neurogenic) (Abrams et al, 2002). The term *idiopathic DO* is a bit of a misnomer, in that the cause of DO in a non-neurogenic patient may be readily apparent (e.g., bladder outlet obstruction [BOO], inflammatory process) or may be truly unknown. Thus, from a practical standpoint, the terms *neurogenic* and *non-neurogenic* DO make more sense, but do not fit the ICS definitions. (It should be noted that the term *neurogenic DO* replaced the term *detrusor hyperreflexia* and the term *idiopathic DO* replaced the term *detrusor instability* in the last ICS terminology). Neurogenic and idiopathic DO may look identical on CMG. These terms are strictly defined by patient neurologic status and not the appearance of the IDCs on CMG.

The presence of DO during UDS must be interpreted in the context of patient symptoms and condition. Ideally, patient symptoms should be reproduced during UDS, so DO would be expected to be accompanied by urgency or urgency incontinence, although it can occur and be significant without being symptomatic, particularly in neurogenic DO. However, DO also can be test induced or clinically insignificant. It has been reported in 14% to 18% of healthy asymptomatic volunteers undergoing UDS (van Waalwijk van Doorn et al, 1992; Robertson, 1999; Wyndaele et al, 2002). This is even more dramatic in ambulatory UDS studies in which the presence of DO has been found in as many as 69% of asymptomatic females (van Waalwijk van Doorn et al, 1996). Conversely, failure to demonstrate DO on UDS does not rule out its existence. It is well known that up to 50% of women with urgency incontinence do not demonstrate DO on UDS. However, the ability to suppress DO during UDS testing may in and of itself be significant. For example, Osman (2003) demonstrated that patients with mixed incontinence and normal CMG findings (no DO) not only had excellent cure rates for stress incontinence but also had an 87% cure rate for urgency incontinence (compared to only 43%

Figure 73-3. Normal, idealized adult cystometrogram with low pressure storage until the patient is given the command to void and the voiding phase starts. Note that the baseline bladder pressure is near zero (compliant) and there are no involuntary contractions.

Figure 73-4. Detrusor overactivity. In this tracing there are two involuntary detrusor contractions (arrows). There is a rise in Pves with no associated rise in Pabd, and therefore the subtracted Pdet looks identical to the Pves.

ture for urgency incontinence for women randomized to receive antimuscarinic medication instead of stress incontinence surgery).

It is important that the person performing the UDS study be absolutely sure that the contraction is indeed involuntary. Sometimes patients may become confused during the study and actually void as soon as they feel the desire. The volume at which contractions occur and the pressure of the contractions should be recorded. It is often worthwhile to repeat CMG at a slower filling rate if the patient experiences uncharacteristic symptoms associated with DO. If the patient experiences incontinence during an involuntary contraction (DO incontinence), this should be noted.

In addition to the presence of DO, its characteristics can be noted. DO can be observed as a single event or as multiple IDCs. It can be phasic (continuous), sporadic, or terminal (occurring at the end of filling near capacity). It also can be suppressed or non-abortable and may lead to leakage or precipitant micturition. Classifying DO in such a way can be valuable in certain circumstances. For example, overactive bladder symptoms associated with obstruction have been shown to have a higher likelihood of resolving with intervention (e.g., transurethral resection of the prostate [TURP]) when DO occurs as a single terminal IDC rather than continuous or sporadic IDCs (Kageyama et al, 2000).

The detection of DO can be influenced by the patient's position. A review of studies on the influence of patient position found that 14 of 16 showed a higher incidence of DO in the vertical position (supine or standing) or onset of DO when changing to a vertical position versus supine (Al-Hayek et al, 2008). Thus, when the detection/documentation of DO is clinically important, it would seem appropriate to test patients in the position in which they experience specific symptoms.

In summary, DO is often a significant UDS observation and may explain a number of storage symptoms. In addition to its presence, the characteristics of DO should be noted. It is also important that clinicians recognize normal test-retest variation and also that "usual LUT behavior" is not always replicated in the test setting.

The vesicoelastic properties of the bladder, based on its composition of smooth muscle, collagen, and elastin, normally produce a highly compliant structure. Therefore as the bladder fills there is little change in pressure (see normalized CMG, Fig. 73-3). Compliance is the relationship between change in bladder volume and change in Pdet ($\Delta \text{volume}/\Delta \text{pressure}$) and is measured in milliliters per centimeters of H₂O. The ICS recommends two standard points, the Pdet at start of bladder filling (usually zero) and the Pdet at cystometric capacity or before the start of any detrusor contraction that results in significant leakage (Abrams et al, 2002). Both points are measured, excluding any detrusor contractions. It is difficult to define what "normal compliance" is in terms of milliliters per centimeters of H₂O. Several authors have shown that mean values for compliance in healthy subjects range from 46 to 124 mL/cm H₂O (Sorensen et al, 1988; van Waalwijk van Doorn et al, 1992; Hosker, 2004). However, there is great variation; for example, van Waalwijk van Doorn and colleagues (1992) showed a variation of compliance from 11 to 150 mL/cm H₂O (mean 46 mL/cm H₂O) in 17 healthy subjects. Some of the variation in a "normal" bladder is likely due to the fact that compliance per se depends on bladder capacity. Furthermore, various definitions of impaired compliance have been used (e.g., between 10 and 20 mL/cm H₂O); however, there is not a consistent definition based on milliliters per centimeters of H₂O. Stöhrer and associates (1999) suggest that a value less than 20 mL/cm H₂O is consistent with impaired compliance and implies a poorly accommodating bladder. However, examples can be cited (e.g., small cystometric capacity) in which this may not be the case. Therefore, in practical terms, absolute pressure is probably more useful than a compliance number or value. For example, it has been shown that storage greater than 40 cm H₂O is associated with harmful effects on the upper tract (McGuire et al, 1981) (Fig. 73-5). Also, depending on the clinical scenario, a particular compliance in terms of milliliters per centimeters of H₂O can mean very different things (Fig. 73-6). As a general rule, prolonged storage at high pressures can lead to upper tract deterioration. Elevated

Figure 73-5. Impaired compliance. Note the rise in Pves (and Pdet) with bladder filling. The Pdet at the end of filling is approximately 45 cm H₂O, which is a potentially dangerous situation. In this case the bladder was filled to a volume of 300 mL, so the compliance is 6.67 mL/cm H₂O. The arrow is the point at which incontinence was demonstrated, which is the detrusor leak point pressure (DLPP).

Figure 73-6. A problem with measuring compliance. Two theoretical cystometrography (CMG) images are shown. The one on the left demonstrates impaired compliance with a constant rise in Pdet throughout filling. At 400 mL the Pdet is 50 cm H₂O (8 mL/cm H₂O), a dangerous situation. There is significant storage time in which the Pdet is greater than 40 cm H₂O. The CMG on the right could represent a small capacity bladder with detrusor overactivity and precipitant micturition. At a volume of only 40 mL, an involuntary detrusor contraction occurs. The Pdet just before this was only 5 cm H₂O. The calculated compliance would be 6 mL/cm H₂O, the same as the one on the left. Yet the CMG on the right does not demonstrate a dangerous situation, just a highly symptomatic (incontinent) patient.

storage pressures and impaired compliance should be interpreted in the context of the clinical scenario. It appears that conventional CMG may provoke filling pressures higher than natural filling in some cases. Robertson (1999) showed that for six patients with neuropathic bladder and severely impaired compliance on conventional CMG, compliance was actually normal on ambulatory monitoring with natural filling.

Impaired compliance is seen in a variety of neurologic conditions (spinal cord injury/lesion, spina bifida) and usually results from increased outlet resistance (e.g., detrusor external sphincter dyssynergia [DESD]) or decentralization in the case of lower motor neuron lesions. It also can result from long-term BOO (e.g., from benign prostatic obstruction) (Leng and McGuire, 2003) or structural changes such as radiation cystitis or tuberculosis. Impaired compliance with prolonged elevated storage pressures is a urodynamic risk factor and usually needs to be treated to prevent renal damage (see Box 73-1).

The measurement of compliance can be affected by a number of factors. Sometimes an increase in Pdet during CMG is seen as a result of rapid filling (filling during CMG is almost always faster than physiologic filling). This is more of an accommodation problem than a true decrease in compliance. When Pdet is seen to be rising, filling may need to be stopped or reduced to see if the effect is real. An IDC, particularly if of a sustained and low amplitude, can be confused with impaired compliance. If filling is stopped, and the pressure returns to baseline, the compliance is not impaired. Finally there are a number of pop-off mechanisms that can make compliance seem better than it actually is. Vesicoureteral reflux (VUR) and bladder diverticulum are two examples. With VUR, pressure is actually transferred to the refluxing renal unit and may be harmful. We have seen instances in which the upper tract holds more urine than the bladder. VUDS (see later) is very useful in these cases. A bladder diverticulum is actually part of the bladder, and thus it may provide a protective effect for the upper tracts. Finally, an incompetent outlet may be a pop-off mechanism. This may become apparent only when outlet resistance is increased. This can be done during CMG by occluding the outlet, but may not be seen until the outlet resistance is surgically increased (e.g., with an artificial urinary sphincter or sling procedure).

Leak Point Pressures

There are two distinct types of leak point pressures that can be measured in the incontinent patient: ALPP and detrusor leak point pressure (DLPP). The two are independent of each other and conceptually measure completely different things.

ALPP is a measure of sphincter strength or the ability of the sphincter to resist changes in Pabd (McGuire et al, 1993). ALPP is defined as the intravesical pressure at which urine leakage occurs as a result of increased Pabd in the absence of a detrusor contraction (Abrams et al, 2002). This measure of intrinsic urethral function is applicable to patients with stress incontinence. An ALPP can be demonstrated only in a patient with SUI. Conceptually, the lower the ALPP, the weaker is the sphincter. There is no normal ALPP, because patients without stress incontinence will not leak at any physiologic Pabd. ALPP should be measured as the total Pabd required to cause leakage, not the change in pressure (McGuire et al, 1993). Therefore, if ALPP is measured in the standing position, it should include the baseline Pabd (or Pves), which is usually approximately 20 to 40 cm H₂O. Classically, the reading is taken from the Pves channel as long as there is no involuntary contraction (Fig. 73-7). In cases in which patients do not leak with a urethral catheter in place, the ALPP can be measured from the Pabd channel either rectally or vaginally (Stöhrer et al, 1999). The original description of ALPP was done at an arbitrary

bladder volume of 150 mL; however, in some cases it is necessary to fill the bladder more. The volume at which ALPP is determined should be noted, because some investigators have found that it decreases at higher volumes (Faerber and Vashi, 1998). As a general rule, we will start testing at 150 mL and then every 50 mL thereafter until SUI is demonstrated. If no SUI is demonstrated at capacity, the urethral catheter is removed and ALPP is measured via the rectal catheter (provided there is no increase in Pdet from DO or impaired compliance).

Attempts have been made to quantify intrinsic sphincter deficiency (ISD) in women using ALPP. In 1993, McGuire and associates measured ALPP in 125 women with SUI. When the ALPP was less than 60 cm H₂O, all patients had high-grade incontinence, with 81% having continuous leakage and 75% having a fixed urethra (no urethral hypermobility). When ALPP was between 61 and 89 cm H₂O, 80% had pronounced urethral hypermobility and moderate to high-grade incontinence. When ALPP was 90 cm H₂O or greater, patients had lesser grades of incontinence and minimal to gross urethral hypermobility. The inference is that:

ALPP < 60 cm H₂O signifies ISD

ALPP between 60 and 90 cm H₂O is equivocal
(there is a component of ISD)

ALPP > 90 cm H₂O indicates little or no ISD

Current technology does not permit a method to distinguish between ISD in the face of urethral hypermobility in women. Therefore, although these ALPP values are often used as guidelines, they should be interpreted with caution. For example, if there is no urethral hypermobility, SUI must be caused by ISD, regardless of the ALPP. Furthermore, Fleischmann and colleagues (2003) found that urethral hypermobility was equally common in women with lower versus higher ALPP. ISD and urethral hypermobility may coexist, and they do not define discrete classes of patients with SUI. Thus an isolated measure of ALPP without considering other factors such as CMG and urethral mobility is of limited utility in predicting success for commonly performed female SUI procedures (Hosker et al, 2009; Rosier et al, 2013). The use of ALPP in the diagnosis and treatment of female SUI is discussed further in that section (see later).

The term ALPP has been used interchangeably with Valsalva leak point pressure (VLPP); however, this is not entirely correct. An ALPP can be measured during UDS testing by a voluntary Valsalva maneuver (VLPP) or by a cough (cough leak point pressure [CLPP]). In the same person, VLPP tends to be significantly lower than CLPP. Therefore exact terminology and methods should be used when describing an ALPP. ALPP also can be influenced by the presence or the size of a urethral catheter (Bump et al, 1995; Huckabay et al, 2005; Türker et al, 2010). It has been shown in women with SUI that the larger the catheter, the lower the ALPP. ALPP also can be measured without a urethral catheter by assessing the Pabd via a rectal (or vaginal catheter). It has been shown that 15% of women with SUI (Türker et al, 2010) and 35% of men with SUI after prostatectomy (Huckabay et al, 2005) will demonstrate an ALPP only with the urethral catheter removed.

The second type of leak point pressure is the DLPP, which is a measure of Pdet in a patient with decreased bladder compliance. It is defined as the lowest Pdet at which urine leakage occurs in the absence of either a detrusor contraction or increased Pabd (Abrams et al, 2002) (see Fig. 73-5). The higher the urethral resistance, the higher the DLPP will be. One can imagine that in a poorly compliant bladder, if outlet resistance is low, incontinence will occur at a relatively low or "safe" pressure. However, if outlet resistance is high, the pressure in the bladder will continue to increase as the bladder fills. There is potentially less incontinence, but eventually the pressure is transmitted to the upper tracts (Fig. 73-8).

From a clinical perspective, DLPP is most useful in patients with upper motor neuron lesions with high storage pressures (usually secondary to DO and DESD), in patients with lower motor neuron

Figure 73-7. Abdominal leak point pressure measurement (ALPP). After progressive Valsalva maneuvers, leakage is demonstrated on the last one at 109 cm H₂O (arrow). There is no rise in Pdet.

Figure 73-8. Outlet resistance causes impaired compliance. Urodynamics (UDS) studies of two children with the same neurologic problem and symptoms, but dramatically different findings. **A**, UDS tracing of a young boy with spina bifida who is incontinent between catheterizations. The study shows a low-pressure system with poor outlet resistance and stress incontinence (abdominal leak pressure point [ALPP] demonstrated) and a low detrusor leak pressure point (DLPP). His upper tracts are protected. **B**, UDS tracing of a young girl with spina bifida who is incontinent between catheterizations. The study shows a high-pressure system with strong outlet resistance and a high DLPP. There was no stress incontinence. Her upper tracts are at risk. The difference in these two cases is difference in storage pressures caused by the difference in outlet resistance.

disease causing “decentralization,” and in non-neurogenic patients with low bladder compliance (after multiple bladder surgeries, radiation, and tuberculous cystitis). The higher the DLPP, the more likely is upper tract damage as intravesical pressure is transferred to the kidneys. McGuire and associates (1981) documented the deleterious effects that a high DLPP has on the upper urinary tracts; a DLPP greater than 40 cm H₂O resulted in hydronephrosis or VUR in 85% of myelodysplastic patients. Although 40 cm H₂O clearly appears to be detrimental in the pediatric population that was studied, most experts would agree that there is limited evidence that an absolute cutoff of 40 cm H₂O should be used to determine a “safe” storage pressure. In reality, when treating impaired compliance, expert opinion leans toward the concept of aiming for as low a pressure as is “reasonably achievable” (Rosier et al, 2013). This would be considerably below 40 cm H₂O in most cases.

The significance of an elevated DLPP is that bladder pressures are getting too high before the pop-off mechanism of urethral leakage occurs. In most cases treatment is aimed at lowering bladder pressures so the DLPP is never reached. In some cases DLPP can be lowered by decreasing outlet resistance—for example, with a sphincterotomy in a patient with DESD.

In summary, ALPP and DLPP, although both called *leak point pressure*, are completely different. The ALPP measures the sphincter response to increased Pabd. The lower the ALPP, the weaker the sphincter. The DLPP measures the injured bladder response to increased outlet resistance. The higher the resistance (e.g., DESD), the higher the DLPP, which is potentially dangerous to the upper tracts.

Stress-Induced Detrusor Overactivity

Sometimes DO can be triggered by a rise in Pabd (Fig. 73-9). Thus the symptom may appear to be stress incontinence, but the condition causing the symptom is actually an involuntary contraction, not sphincteric weakness. In a patient with stress-induced DO (SIDO) it is important to note if there is also urodynamic SUI and/or DO independent of the SIDO.

Occult Stress Incontinence

Stress incontinence on prolapse reduction, also referred to as *occult incontinence* or *latent stress incontinence*, is stress inconti-

Figure 73-9. Stress-induced detrusor overactivity (SIDO). In this case, there are three episodes of detrusor overactivity (DO) preceding two episodes of SIDO. In the case of SIDO, note that as Pabd increases so does Pves. Shortly after this, Pdet rises and continues long after Pabd returns to baseline. With both episodes of SIDO, incontinence occurred, as can be seen on the flow (Qura) curve. Vura, urine volume voided. (From Nitti VW. Cystometry and abdominal pressure monitoring. In Nitti VW, editor. Practical urodynamics. Philadelphia: Saunders; 1998. p. 38–51.)

nence that is demonstrated in a clinically continent woman with pelvic prolapse, only when the prolapse is reduced (Ballert et al, 2009; Haylen et al, 2010). Prolapse reduction can be done with a pessary, packing, forceps, or manually. Technically, if this is demonstrated during urodynamic testing, it may be referred to as *urodynamic occult SUI*.

Urethral Pressure Profilometry

The method of urethral pressure profilometry (UPP) was popularized by Brown and Wickman in 1969 using a small catheter with lateral apertures through which fluid is continuously infused. Simultaneous bladder and urethral pressure is measured as the catheter is slowly withdrawn along the course of the urethra. The urethral pressure transducer measures the fluid pressure required to

Figure 73-10. Urethral pressure profile with appropriate parameters identified.

lift the urethral wall off the catheter side holes and thus elevates the circumferential and radial stresses induced by the presence of the catheter in the urethra and the slow urethral profusion. Thus urethral pressure is defined as the fluid pressure needed to just open a closed urethra (Abrams et al, 2002). Accurate measurements are recorded only in cases in which the urethra is distensible and therefore able to create a perfect seal.

Despite an abundant literature on urethral profilometry, its clinical relevance is controversial. Many urologists do not routinely perform urethral profilometry. The UPP represents the intraluminal pressure along the length of the urethra in graphic form (Fig. 73-10). Several parameters can be obtained from the UPP:

- The urethral closure pressure profile is given by the subtraction of intravesical pressure from urethral pressure.
- Maximum urethral pressure is the highest pressure measured along the UPP.
- Maximum urethral closure pressure (MUCP) is the maximum difference between the urethral pressure and the intravesical pressure.
- Functional profile length is the length of the urethra along which the urethral pressure exceeds intravesical pressure in women.

In most continent women the functional urethral length is approximately 3 cm and the MUCP is 40 to 60 cm H₂O, but normal values vary widely. MUCP also has been used to define ISD. McGuire (1981) performed a retrospective evaluation of women who failed SUI surgery and found that a preoperative MUCP of 20 cm H₂O or less resulted in higher surgical failure rates. These patients represented a specific subtype of SUI caused by a fixed, open urethra (type III SUI). In 1992, the term was redefined as ISD. Many authors have used the definition of MUCP of 20 cm H₂O or less to define ISD; however, this definition has many of the same problems as ISD definitions for ALPP. Another caveat of UPP is that its measurement does not diagnose stress incontinence and SUI is not required to measure it (contrary to ALPP). MUCP in incontinent women has been shown to be lower than in continent women, but there is certainly overlap (Schick et al, 2004). In addition, MUCP is not always indicative of the severity of incontinence. For example, there is a difference between the urethra of an incontinent patient whose MUCP was 38 cm H₂O and that of a continent woman with the same MUCP.

In 2002, the ICS standardization subcommittee concluded that the clinical utility of urethral pressure measurement is unclear (Lose et al, 2002). Furthermore, there are no urethral pressure measurements that (1) discriminate urethral incompetence from other disorders; (2) provide a measure of the severity of the condition; or (3) provide a reliable indicator to surgical success and return to normal after surgical intervention (Lose et al, 2002). In 2013, Rosier and associates reported that since the 2002 ICS report there is no new evidence, nor evidence regarding newer techniques, that intrinsic urethral pressure measuring quality has improved to a clinically relevant level with regard to sensitivity, specificity, and reliability.

Figure 73-11. Schematic pressure flow study labeled with recommended terminology.

VOIDING AND EMPTYING PHASE

Normal Voiding and Emptying

Evaluation of the voiding phase provides an assessment of both detrusor contractility and bladder outlet resistance, the two parameters that are critical for normal bladder emptying. In simple terms, abnormalities of bladder emptying are caused by “overactivity” of the bladder outlet (too much outlet resistance), “underactivity” of the detrusor (weak detrusor contraction force, short detrusor contraction duration, impaired contraction velocity), or a combination of both. The simultaneous measurement of Pdet and urinary flow rate during voluntary voiding, known as a pressure-flow study, is the most accurate way to access these two critical parameters (Fig. 73-11).

To understand the relationship between bladder contractility and outlet resistance, one must start with an understanding of the normal micturition process. Normal voiding is accomplished by activation of micturition reflex, which involves the following (Fig. 73-12):

1. Relaxation of striated urethral sphincter
2. Contraction of detrusor muscle
3. Opening of vesical neck and urethra
4. Onset of urine flow

This occurs as a result of coordination between pontine and sacral micturition centers with suprapontine input that allows for voluntary control of the micturition reflex.

UDS can evaluate the critical parameters during the voiding phase, which include detrusor contractility, relaxation of the bladder outlet, and coordination of sphincters (Fig. 73-13).

According to the ICS, normal detrusor function is characterized by a voluntarily initiated continuous contraction that leads to complete bladder emptying within a normal time span and in the absence of obstruction. DU is defined as when there is a contraction of reduced strength and/or duration resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span. Finally, an acontractile detrusor is when there is no demonstrable contraction during UDS (Abrams et al, 2002). The term *areflexia* has been used in the case of a neurologic cause of an acontractile detrusor, but it is now suggested that this be replaced by *neurogenic acontractile detrusor*, when appropriate (Haylen et al, 2010).

Figure 73-12. Physiology of micturition. See text for details. EMG, electromyography; ext, external. (From Blaivas JG. Pathophysiology of lower urinary tract dysfunction. Clin Obstet Gynaecol 1985;12:295–309.)

Figure 73-13. Multichannel urodynamics study showing filling and voiding phases with pressure and electromyography (EMG) readings. In this case, the patient experienced an involuntary detrusor contraction (IDC), which led to increased external sphincter contraction and an increase in EMG activity (guarding reflex). However, shortly after that the patient is given permission to void. First there is quieting of the EMG (sphincter relaxation) followed by an increase in Pdet and volitional voiding with a normal appearing uroflow curve.

The current definition of *detrusor underactivity* is hampered by the subjective interpretation of what constitutes reduced strength, reduced length of contraction, or prolonged emptying (Osman et al, 2014). Normal detrusor function and DU are somewhat nebulously defined in terms of absolute pressure because bladder pressure is influenced by outlet resistance. When evaluating detrusor function urodynamically, UDS must be correlated with clinical findings. For example, if a patient who normally voids is unable to void during a UDS study, a definitive diagnosis of acontractile detrusor cannot be made. Specific measures of detrusor contractility are mentioned later in the text.

Urinary flow rate in combination with PVR is a useful clinical tool to assess emptying. Reduced flow rate or elevated PVR indicates that emptying is not complete but does not inform as to why (e.g., obstruction vs. impaired contractility). Flow rate also depends on voided volume because there is a linear relationship between Qmax and voided volume, with a voided volume above and a hyperbolic relationship below a voided volume of 150 mL (Drach et al, 1979).

Therefore many authors recommend a minimum voided volume of 150 mL to accurately assess uroflow. However, establishing a minimum voided volume puts major limitations on uroflowmetry because any patients with voiding dysfunction do not routinely void large enough volumes to be evaluable. The corrected form of Qmax—Qmax divided by the square root of voided volume—may provide useful information in such patients (Boone and Kim, 1998). Over the years several nomograms have been developed to define normal flow rates for a specified population and correct for voided volume. These include the Siroky nomogram (Siroky et al, 1979, 1980) for men and the Liverpool nomogram (Haylen et al, 1989) for men and women.

The **bethanechol supersensitivity test** has been used to help distinguish the cause of DU as neurogenic or myogenic. It is based on the Cannon law of denervation, which states that denervated structures develop increased sensitivity to chemical stimulation. This concept was applied to the bladder by Lapidès and associates (1962). The original bethanechol supersensitivity test described by these authors was performed by infusing liquid at a rate of 1 mL/sec to a volume of 100 mL, where the pressure is measured. This can be done up to three times and the pressure values averaged. The patient is then given 2.5 mg of bethanechol chloride (later revised to 0.035 mg/kg) subcutaneously and the study is repeated at 10, 20, and 30 minutes. A normal bladder (or myogenically impaired bladder) should show an increase of less than 15 cm H₂O above control value at 100 mL at 30 minutes. This is considered a negative study result. A positive study result, indicating a sensory or motor paralytic bladder, is a response of at least 15 cm H₂O above the control value. More recent studies have indicated that the bethanechol supersensitivity test is rather unreliable in predicting neurogenic bladder. Blaivas and colleagues (1980) reported only 76% sensitivity and 50% specificity in doing this. Another problem is that even if the test is able to differentiate between neurogenic and myogenic dysfunction, treatment is often the same (e.g., clean intermittent catheterization). Bethanechol chloride, whether administered subcutaneously or orally, has not proved to be a consistently effective treatment for the underactive detrusor (Wein et al, 1978, 1980). In addition a positive test does not predict improved voiding when it is used therapeutically. Therefore we feel that there is a very limited role for the use of the bethanechol supersensitivity test.

Voiding Pressure-Flow Studies

Once the bladder is filled to cystometric capacity, the voiding portion of the pressure-flow study can begin. This examines the emptying phase of micturition. The same bladder and rectal (or vaginal catheter in women) catheters are used while simultaneously collecting pressure data along with uroflowmetry. Ideally, such a study should assess a voluntary void. When there is flow of urine during an IDC, patients may contract the pelvic floor to prevent leakage. Such an event should be annotated on study. In addition, some patients may have a difficult time voiding on demand in a public setting and with invasive monitoring in place. These stressors and the artificial environment of the testing need to be accounted for when interpreting the test.

As mentioned previously, Pdet during voiding is a function of outlet resistance. For a normal detrusor, the greater the outlet resistance, the higher the Pdet during voiding will be. This is accompanied by a reduced flow rate. A healthy bladder is able to overcome obstruction by contracting more forcefully, and although flow may be slower the bladder is able to empty itself. Over time, the detrusor may decompensate and may no longer be able to generate the necessary pressure to overcome obstruction. When this occurs the result will be incomplete bladder emptying or retention of urine.

The voiding pressure-flow study helps assess two critical parameters related to the bladder and bladder outlet: detrusor activity (normal vs. impaired) and outlet resistance (obstructed vs. unobstructed). In general the pressure-flow study can identify the following three fundamental conditions:

1. Low (or normal) Pdet and high (or normal) flow rate (normal, unobstructed voiding)
2. High Pdet and low (or normal) flow rate (obstruction)
3. Low Pdet with low flow rate (DU)

It is important to remember that these three categories are broad and general and a final diagnosis should be made after considering UDS findings and the patient's clinical presentation (see later). It is also important to note that in cases of DU (i.e., low Pdet and low flow) obstruction may coexist with DU, but making the urodynamic diagnosis of obstruction may not be possible if the detrusor is too decompensated.

The urodynamic manifestation of BOO is high-pressure and low-flow voiding (or more practically speaking increased pressure and reduced flow). Over time, if bladder decompensation results, DU or impaired contractility can result.

To use the common measures of obstruction and impaired contractility that are used today it is important to understand basic bladder output and urethral resistance relations (URRs). Attempts to mathematically define urethral resistance date back to 1962 (Gleason and Lattimer, 1962). Early equations calculating urethral resistance followed standard hydrodynamic formulae calculating outlet resistance. These concepts failed to consider that the urethra is not a rigid tube but rather has an active and distensible nature. They also failed to consider the importance of bladder volume. Rigid tube hydrodynamics were abandoned in favor of more dynamic ways to analyze micturition. In 1972, Griffiths introduced bladder output relation (BOR), which depicts the interrelations between bladder pressure and uroflow at a given volume and essentially measures the function of the bladder independent of the function of the urethra (Griffiths, 1973). Griffiths further defined a method to evaluate urethral resistance independent of bladder function, the URR. According to this relation, as bladder pressure rises the flow rate will be zero until the intrinsic bladder pressure equals the intrinsic urethral pressure. At this point flow will start and the flow rate will rise rapidly, with further increases in the intrinsic bladder pressure. If pairs of simultaneously measured values of Pdet and flow rate are plotted against one another throughout the course of a micturition event, a curve is obtained that shows the resistance to flow independent of detrusor function, representing the URR. If the urethra were relaxed or tightened during voiding, the URR would move toward the left or right, respectively. Because the BOR represents the function of the bladder independent of the urethra and the URR depicts urethral function independent of bladder function, the actual Pdet and flow rate are determined by the intersection of the BOR and the URR, which is the point at which intrinsic bladder pressure equals urethral pressure (Fig. 73-14). A change in one of these relations during micturition would not affect the curve representing the other relation but would result in the point of intersection to moving along that curve.

In cases of suspected DU a stop test can be performed. This is done by voluntary or mechanical interruption of urine flow during voiding (i.e., occluding the urethra). This allows for an estimation of isovolumetric Pdet (Piso) (Sullivan and Yalla, 2007). In a voluntary stop test, patients interrupt flow midstream by contracting the external urethral sphincter. In a mechanical stop test, interruption involves blocking the urethra by pulling a catheter balloon against the bladder neck during midstream or clamping or squeezing the urethra. In a continuous occlusion test, the outflow is occluded before the onset of detrusor contraction and the patient is asked to void against the occlusion. The three techniques show good correlation with each other in both men (Sullivan et al, 1995) and women (Tan et al, 2003). However, the voluntary stop test gives a lower Piso than the other two (Sullivan et al, 1995).

Bladder Outlet Obstruction and Detrusor Underactivity in Men

The value of making a precise diagnosis of obstruction in men comes from the assumption that the outcomes of surgery to treat benign prostatic hyperplasia (BPH) and its consequent LUTS are

Figure 73-14. Relationship between Pdet and flow in a given person—the bladder outlet relation (BOR). See text for details. (From Griffiths DJ. The mechanics of the urethra and of micturition. *Br J Urol* 1973;45:497–507.)

improved when obstruction can be documented. BPH and benign prostatic obstruction (BPO) are highly prevalent conditions, so it was intuitive to use them as a model for defining obstruction. Most of the analytical work has focused on defining obstruction-based pressure-flow studies. Three well-known nomograms based on pressure-flow studies have been described to diagnose men as obstructed, equivocal, or unobstructed. These are the Abrams-Griffiths nomogram (Abrams and Griffiths, 1979), the Urethral Resistance Factor (URA) (Griffiths et al, 1989), and the Linear Passive Urethral Resistance Relation or Schafer nomogram (Schafer, 1990). The categories of obstruction described in these nomograms are based on observations of men who underwent surgery for LUTS (mainly TURP). After surgery the Pdet at maximum flow (PdetQmax) was reduced in the obstructed group, reduced unpredictably in the equivocal group, and unchanged in the unobstructed group. Subsequently, Lim and Abrams (1995) showed that patients were similarly classified by all three methods. They described a number, the Abrams-Griffiths (AG) number (now known as the bladder outlet obstruction index [BOOI]) derived from the equation for the slope of the line dividing obstructed from equivocal in the Abrams-Griffiths nomogram, which is the same line dividing obstructed from slightly obstructed in the Schafer nomogram: $BOOI = PdetQ_{max} - 2(Q_{max})$. Subsequently Griffiths and colleagues (1997) (Fig. 73-15) described the ICS provisional nomogram, which is now suggested for use for the diagnosis of obstruction in men with LUTS suggestive of BPH (Abrams, 1999). Men are considered obstructed if the BOOI is 40 or greater, unobstructed if the BOOI is 20 or less, and equivocal if the BOOI is 20 to 40.

Figure 73-15. The Provisional International Continence Society nomogram. See text for details.

Figure 73-16. The Bladder Contractility Nomogram. See text for details.

Voiding pressure-flow studies show consistent reproducibility in the diagnosis of BOO in men. In a review of the topic, [Abrams and colleagues \(2001\)](#) concluded that random variations of approximately 9 to 14 cm H₂O in pressure measurement and approximately 0.4 to 2 mL/sec in maximum flow rate occur. In repeated studies during the same session there is usually a systematic decrease of up to 4 cm H₂O in Pdet and 0.4 mL/sec in maximum flow rate. These variations have little clinical importance because they cause only 10% to 16% of patients to change classification on the ICS nomogram, and in all but approximately 1% that change is only by 1 class (e.g., from equivocal to unobstructed or from obstructed to equivocal).

Although much effort has focused on defining outlet resistance (i.e., obstruction), an index for bladder contractility also can be derived from the contractility groups [Schafer \(1995\)](#) described (strong, normal, weak, very weak). The slope of Schafer's lines, now known as the bladder contractility index (BCI), is given by the formula: $PdetQmax + 5(Qmax)$ ([Abrams, 1999](#)). Strong contractility is a BCI greater than 150, normal contractility with a BCI of 100 to 150, and weak contractility with a BCI of less than 100 ([Fig. 73-16](#)). The BCI is the most common measure of bladder contractility used today because of its easy calculation and relationship to the BOOI and ICS nomogram.

Although contractility and obstruction can be independently measured, it is sometimes impossible to diagnose obstruction in the face of DU using the ICS or other nomograms. For example, to make a diagnosis of unequivocal obstruction, BOOI must be at least 40 cm H₂O. That means that a Pdet of at least 40 cm H₂O must be generated and that assumes flow is zero. If the Qmax is 5 mL/sec, then PdetQmax must be at least 50 cm H₂O. Thus the ICS nomogram can exclude obstructed patients whose impaired contractility is the result of long-term obstruction. In such cases clinical judgment becomes important.

Another measure of detrusor function is the Watts factor (WF), a quantification of detrusor power by a formula that estimates the power per unit area of bladder surface generated by the detrusor, corrected for the finite power required for either isometric contraction or for shortening against no load.

$$WF = [(Pdet + a)(Vdet + b) - ab] / 2\pi$$

where Vdet represents detrusor shortening velocity and a and b are fixed constants ($a = 25$ cm H₂O; $b = 6$ mm/sec), obtained from experimental and clinical studies ([Griffiths, 1991](#)).

Because Pdet and velocity vary during the voiding phase, so too does the WF. Two points have been proposed as the most representative of detrusor contractility: the maximum WF (WFmax) ([Griffiths et al, 1989](#)) and the WF at maximum flow (Wqmax). An advantage of the WF calculation is that it depends minimally on bladder volume ([Griffiths, 1991](#)) and is not affected by the presence of BOO ([Lecanwasam et al, 1998](#)). However, it does not provide a measure of contraction sustainability and involves a complex calculation, limiting its use in clinical practice ([Osman et al, 2014](#)). In addition, threshold values for normal have not been validated; however, some have suggested using a Wmax value of 7.0 W/m² ([van Koeveeringe et al, 2011](#)).

BOO is associated with abnormalities of storage as well. This is presumably due to changes in ultrastructure that occur with obstruction. DO and impaired compliance occur in conjunction with obstruction. For example, approximately two thirds of men with symptomatic BPO have DO that resolves 50% to 67% of the time with treatment of obstruction ([Abrams et al, 1979](#)). Reduced compliance is also associated with obstruction and has been shown to improve with treatment of obstruction (TURP) ([Leng and McGuire, 2003](#)).

An alternative to voiding pressure-flow studies as a way of measuring outlet resistance is the micturitional urethral pressure profile (MUPP), or voiding profilometry. This technique, popularized by [Yalla and colleagues \(1980, 1981\)](#), can both diagnose and localize obstruction. The MUPP is performed with a triple-lumen catheter under fluoroscopic guidance, similar to the static UPP described previously. During voiding the catheter is slowly withdrawn and the pressure is measured from the bladder neck through the anterior urethra ([Steele et al, 1998](#)). Normally, during voiding the pressure in the bladder is isobaric with the prostatic urethra and then pressure decreases across the membranous urethra and gradually decays along the rest of the anterior urethra. The membranous urethra is the narrowest segment of the bladder outlet during voiding, which accounts for the expected pressure drop of 20 to 30 cm H₂O. In patients with obstruction secondary to BPH, the MUPP is quite different. A pressure disparity somewhere along the prostatic urethra typically will be seen. When this pressure disparity is greater than 5 cm H₂O, obstruction at the point of pressure drop is present. MUPP has been shown to be as effective in diagnosing BOO as standard pressure-flow studies ([DuBeau et al, 1995](#)). An analysis of patients with symptomatic BPH has shown that successful treatment outcomes have been achieved with treatment based on MUPP results ([Lecanwasam et al, 1994](#)).

In cases in which it is difficult to differentiate obstruction from DU by standard pressure-flow dynamics (e.g., in men with inefficient emptying in whom neither obstruction nor DU can be diagnosed by standard pressure-flow studies), Piso can be measured by a stop test (see earlier discussion). In men a Piso less than 50 cm H₂O is uncommon and has been considered to be diagnostic of DU ([Comiter et al, 1996](#); [Sullivan and Yalla, 1996](#)).

Bladder Outlet Obstruction in Women

BOO in women can present more of a diagnostic dilemma than in men. Because there is no highly prevalent condition (such as BPH) that causes female obstruction it is difficult to establish nomograms. Furthermore, nomograms derived for men cannot be applied to women because voiding dynamics differ. In addition, anatomic differences allow many women to empty their bladders by simply

relaxing the pelvic floor and some will augment voiding by abdominal straining. Minor elevations in Pdet or decreases in flow rate, which might be considered insignificant in the male population, might signify BOO in women. Accordingly, clinicians must have a high index of suspicion based on the presence of LUTS, incomplete emptying, persistent UTIs, and a history of anti-incontinence surgery, prolapse, or other conditions.

In an effort to develop cutoff values for pressure and flow for the diagnosis of obstruction in women, Chassagne and associates (1998) studied a group of "clinically obstructed women" (after incontinence surgery, secondary to cystocele, or "other etiologies") and compared them to a group of controls (women with stress incontinence). Using receiver operating characteristic (ROC) curve analysis, they found the optimum sensitivity and specificity for predicting obstruction was obtained with a Qmax 15 mL/sec or less and a PdetQmax of 20 cm H₂O or greater (74.3% sensitivity and 91.1% specificity). In 2000, with an expanded population, the authors (Lemack and Zimmern, 2000) revised this to Qmax 11 mL/sec or less and PdetQmax 21 cm H₂O or greater, as optimal for the selection of patients with BOO. In the most recent publication (Defreitas et al, 2004), these authors used normal asymptomatic women as the control group and found the highest sensitivity and specificity for predicting obstruction was obtained with Qmax 12 mL/sec or less and PdetQmax 25 cm H₂O or greater. These cut-point studies have some limitations; namely, obstruction was predefined clinically and only patients with anatomic obstruction were included. Women with functional obstruction (e.g., from primary bladder neck obstruction or dysfunctional voiding) were not included in any of the cut-point analyses. This would be a difficult group of women to define clinically without any testing.

In 1999, Nitti and coworkers showed that the addition of fluoroscopic imaging to UDS was helpful in diagnosing female BOO (see section on VUDS). In this study, patients were classified as obstructed if there was radiographic evidence of obstruction between the bladder neck and distal urethra in the presence of a sustained detrusor contraction of any magnitude. In addition to diagnosing BOO it also localizes the site of obstruction and allows for the diagnosis of obstruction in the face of impaired contractility if indeed the site can be localized. With both the video-urodynamic and cut-points criteria there is a significant difference in mean Qmax and PdetQmax in the group of obstructed versus the group of unobstructed women, but there is a large overlap of values between obstructed and unobstructed patients. This demonstrates that absolute pressure and flow values are imprecise and that another parameter (e.g., radiographic or clinical evidence of obstruction) is necessary for diagnosis.

Blaivas and Groutz (2000) presented a nomogram for defining female BOO. Citing the fact that in their series there was a significantly higher flow rate in the same woman without a catheter, they choose to use noninvasive flow rate in their nomogram. Also, because they found no statistical difference between PdetQmax and Pdetmax in obstructed or unobstructed patients, they chose Pdetmax as the pressure parameter. Using cluster analysis to classify patients with low- and moderate-grade obstruction, they formulated the nomogram. The nomogram places women into four zones: no, mild, moderate, and severe obstruction. An obvious criticism of the nomogram is that it is based on two separate voids (invasive and noninvasive) and one must assume that the pressure characteristics of the void are the same. Akikwala and colleagues (2006) compared the three methods of diagnosing BOO in women and found good concordance between the video-urodynamic and cut-points criteria. They also noted that the Blaivas-Groutz nomogram overdiagnosed obstruction compared to the other two methods.

Obstruction in women cannot be defined by the ICS nomogram or the BOOI because these will grossly underestimate female BOO. This is because normally women void at much lower pressures than men and therefore the obstructed female bladder outlet may not respond as dramatically (or at least with the same pressures) as in males. Unfortunately, there is no condition in women that causes BOO as commonly as BPO in men and therefore creating a consistent standard is difficult. Thus the concepts are the

same (higher pressure and lower flow), but the values are different and less well defined. Those who are interested are referred to suggested readings (Nitti et al, 1999; Blaivas and Groutz, 2000; Defreitas et al, 2004; Akikwala et al, 2006).

Theoretically, one can consider measuring Piso via a stop test in women to measure detrusor strength and help differentiate between DU and obstruction. Piso has not been used to accurately characterize women. However, it is known that in older women Piso values are significantly lower than in men. Tan and colleagues (2003) showed mean Piso in women at least 53 years of age with urgency incontinence was 31.2, 47.2, and 48.7 cm H₂O for voluntary, mechanical, and continuous stop test, respectively.

Sphincter Coordination

The External Sphincter

Normal voiding requires external sphincter relaxation followed by contraction of the detrusor. The external sphincter (and internal sphincter) should remain relaxed until voiding is complete. In normal voluntary voiding, a rise in Pdet is preceded by a fall in urethral pressure and relaxation of the external sphincter as measured by EMG. The sphincter and urethral pressure remain low during voiding and then increase when voiding is completed (Fig. 73-17). Failure of the sphincter to relax or stay completely relaxed during micturition is abnormal (Abrams et al, 2002). Thus normally EMG activity decreases before a voluntary bladder contraction; however, it is not abnormal for EMG activity to increase with an involuntary contraction as part of a guarding reflex to inhibit the IDC (see Fig. 73-13).

There are several abnormalities related to external sphincter relaxation (or lack thereof). DESD occurs when there is an involuntary increase of external sphincter activity associated with DO and also with voiding (Fig. 73-18). It is caused by a neurologic lesion in the suprasacral spinal cord. DESD can produce profound changes as the detrusor involuntarily contracts against a relatively closed sphincter. This will result in high pressures and can even cause impaired bladder compliance over time. Because long periods of elevated Pdet during bladder filling or (abnormally prolonged) voiding put the upper urinary tract at risk (McGuire et al, 1996; Kurzrock and Polse, 1998; Tanaka et al, 1999). DESD may be considered a urodynamic risk factor for upper tract deterioration (see Box 73-1). True DESD occurs only

Figure 73-17. Uroynamics (UDS) tracing of a patient with myelodysplasia and neurogenic detrusor overactivity (DO) and detrusor external sphincter dyssynergia (DESD). Note the initial involuntary detrusor contraction associated with DESD and incontinence (measured on the flow channel). With refilling there is again DO with DESD, and then the patient is told to voluntarily void and there is persistent increased electromyography (EMG) activity. As a result there is high-pressure, low-flow voiding (obstruction from the dyssynergic sphincter).

Figure 73-18. Primary bladder neck obstruction in a 35-year-old woman with obstructive voiding symptoms and intermittent urinary retention. Note the failure of the bladder neck to open at all, despite a detrusor contraction of greater than 60 cm H₂O. (From Nitti VW. Primary bladder neck obstruction in men and women. *Rev Urol* 2005;7[Suppl. 8]:S12–7.)

when there is a known neurologic lesion above the sacral micturition center. The higher the lesion, the more likely it is that DESD will occur (Blaivas, 1982). If there is no neurologic lesion, the dyssynergia is considered to be a learned behavior and is known as **dysfunctional voiding**. The term *dysfunctional* describes malfunction (failure to relax or involuntarily contraction of the external sphincter) during the voiding phase only and says nothing about the storage phase (Nevéus et al, 2006). However, it is entirely possible and quite common for a patient to experience storage symptoms (and UDS abnormalities) associated with dysfunctional voiding. Although the condition has been extensively described in children, it also has been described in adult men (Kaplan et al, 1997; Nitti et al, 2001; He et al, 2010) and women (Carlson et al, 2001) and can be a major cause of LUTS. It is recommended that when dysfunctional voiding is diagnosed by UDS, the flow pattern (reduced and/or intermittent) is confirmed by noninvasive uroflowmetry to rule out a test-induced phenomenon (Barrett and Wein, 1981; Carlson et al, 2001). He and colleagues (2010) used the following diagnostic criteria in men: nothing abnormal detected in the history and no symptoms on an examination for neurologic diseases; transient and intermittent closure of the external sphincter during voiding detected by EMG and fluoroscopic cystourethrography; and a higher external sphincter EMG activity with no Pabd increase in the voiding phase. Uroflowmetry was assessed individually to show any discontinuity in a diagram of urinary flow, in conditions with as little external interference as possible.

The Internal Sphincter

Just as there can be a lack of coordination of the detrusor and external sphincter, so too can there be dyscoordination of the internal sphincter or bladder neck. In the case of neurologic disease, if a suprasacral spinal cord lesion is above the level of the sympathetic ganglia (T10 to L1) detrusor internal sphincter dyssynergia may occur in conjunction with external sphincter dyssynergia (Pan et al, 2009). In non-neuropathic men, women, and children the phenomenon of bladder neck dyssynergia or primary bladder neck obstruction is a well-known cause of LUTS, although its exact cause is not known (Diokno et al, 1984; Norlen and Blaivas, 1986; Combs et al, 2005). Conditions of internal sphincter dysfunction require VUDS for an exact diagnosis and are described in the next section.

KEY POINTS: URODYNAMICS PARAMETERS

- Normally, Pdet should remain near zero during the entire filling cycle until voluntary voiding is initiated.
- The ability to calculate subtracted Pdet allows distinguishing between a true rise in Pdet (either via a contraction or loss of compliance) and the effect of increased Pabd.
- It is important that the person performing the UDS study be absolutely sure that a bladder contraction is indeed involuntary. Sometimes patients may become confused during the study and actually void as soon as they feel the desire.
- “Usual LUT behavior” is not always replicated in the test setting.
- As a general rule, prolonged storage at high pressures can lead to upper tract deterioration.
- ALPP and DLPP, although both called *leak point pressure*, are completely different. The ALPP measures the sphincter response to increased Pabd. The lower the ALPP, the “weaker” is the sphincter. The DLPP measures the injured bladder response to increased outlet resistance. The higher the resistance, the higher is the DLPP, which is potentially dangerous to the upper tracts.
- According to the ICS, normal detrusor function is characterized by a voluntarily initiated continuous contraction that leads to complete bladder emptying within a normal time span and in the absence of obstruction.
- According to the ICS, DU is defined as when there is a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying within a normal time span.
- The urodynamic manifestation of BOO is high-pressure and low-flow voiding.
- Normally EMG activity decreases before a voluntary bladder contraction; however, it is not abnormal for EMG activity to increase with an involuntary contraction as part of a guarding reflex to inhibit the IDC.
- True DESD occurs only when there is a known neurologic lesion above the sacral micturition center.

VIDEO-URODYNAMICS

VUDS consists of the simultaneous measurement of UDS parameters and imaging of the lower urinary tract. It provides the most precise evaluation of voiding function and dysfunction and is particularly useful when anatomic structure and function are important (McGuire et al, 1996). Examples of situations in which VUDS is useful include the localization of obstruction, detecting incontinence not seen on physical examination, and evaluating VUR during storage and/or voiding. It can be particularly useful in cases of neuropathic voiding dysfunction. VUDS is the only way to evaluate bladder neck dysfunction and can confirm sphincteric dysfunction diagnosed by EMG. Also, there are instances in which a known anatomic abnormality exists and simultaneous imaging can determine if that abnormality is playing a role in voiding dysfunction (e.g., bladder or urethral diverticulum, VUR).

VUDS can be performed using a variety of different methods. Most commonly fluoroscopy is employed using a C-arm. This gives the most flexibility in allowing patient positioning. However, a fixed unit with a fluoroscopy table that can move from 90 to 180 degrees also may be used. It is important that the patient be able to be positioned properly to evaluate the desired function and anatomy. For example, SUI in men and women is best evaluated in the standing position. Voiding is best evaluated in the position that the patient characteristically voids (usually sitting for women and standing for men). It is always recommended that fluoroscopy time be limited and focus on situations of high yield, such as during provocative maneuvers to demonstrate SUI, during rises in pressure associated with impaired compliance or involuntary contractions, and during voiding.

VUDS can be extremely useful for the diagnosis of BOO in women (Nitti et al, 1999; Blaivas and Groutz, 2000). In 1999, Nitti and colleagues described the VUDS criteria for the diagnosis of obstruction where radiographic evidence of obstruction between the bladder neck and urethral meatus during voluntary voiding defines and localizes obstruction. **Primary bladder neck obstruction can be diagnosed only on VUDS.** Figures 73-18 and 73-19 distinguish between the two most common causes of functional obstruction in women, primary bladder neck obstruction and dysfunctional voiding.

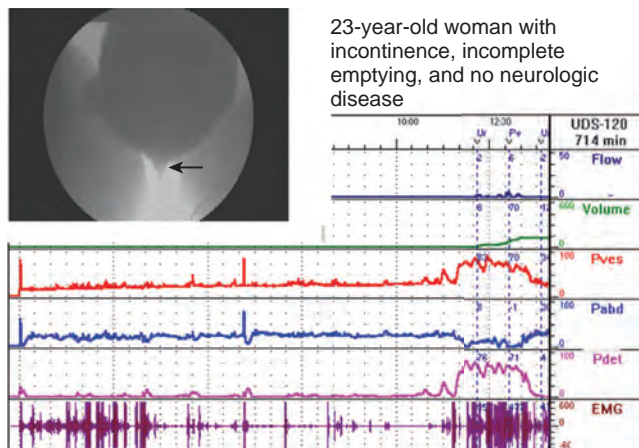

Figure 73-19. Dysfunctional voiding. Uroynamics study of a 23-year-old woman with urgency incontinence, incomplete emptying, and no neurologic disease. Just before voiding there is an involuntary detrusor contraction. With voiding there is increased electromyography (EMG) activity. The fluoroscopic picture taken during voiding shows a characteristic “spinning top urethra” with the level of obstruction at the external sphincter. The high-pressure and low-flow voiding is also characteristic of obstruction.

Similarly, VUDS can be used to evaluate LUTS in young men and in particular make a diagnosis of primary bladder neck obstruction (Norden and Blaivas, 1986; Kaplan et al, 1996). Although obstruction can be diagnosed by pressure-flow studies alone, many surgeons would not feel comfortable performing surgical intervention on a young man without localizing that obstruction. In addition, sometimes bladder neck obstruction can present without the classic findings of high pressure and low flow. Three distinct types have been described (Nitti et al, 2001): classic high pressure–low flow (type I), normal pressure–low flow with narrowing at the bladder neck (type II), and delayed opening of the bladder neck (type III). Figure 73-20 shows types I and II male primary bladder neck obstruction. Fluoroscopy is critical to the diagnosis, especially in types II and III. In fact, simultaneous fluoroscopy during UDS can localize the anatomic site of obstruction in many conditions (e.g., BPO, bladder neck contracture, urethral stricture) once the urodynamic diagnosis of obstruction is confirmed.

VUDS has been shown to be very useful in diagnosing voiding phase dysfunction in women and can be more accurate than surface electrodes in determining EMG activity. We recently found that VUDS was more accurate than surface EMG in diagnosing dysfunctional voiding and differentiating it from primary bladder neck obstruction in women (Brucker et al, 2012). In this study it was assumed that VUDS would be the most accurate method to diagnose voiding phase dysfunction in women. We found that if the surface EMG findings alone were used, the incorrect diagnosis would have been made in 20.6% of the women with dysfunctional voiding diagnosed by VUDS. In contrast, increased EMG activity during voiding was seen in 14.3% of women with primary bladder neck obstruction by VUDS (e.g., a patient voiding with high pressure and low flow without any funneling or opening of the bladder neck and during voiding).

In cases of severe neurogenic and non-neurogenic storage phase dysfunction, VUDS can be helpful if upper urinary tract effects (e.g., hydronephrosis) are present. It has been previously mentioned that upper tract deterioration depends on storage pressures and that reduced bladder compliance is associated with such changes. However, if VUR occurs as a result of high bladder storage pressures, this can result in a pop-off mechanism causing true

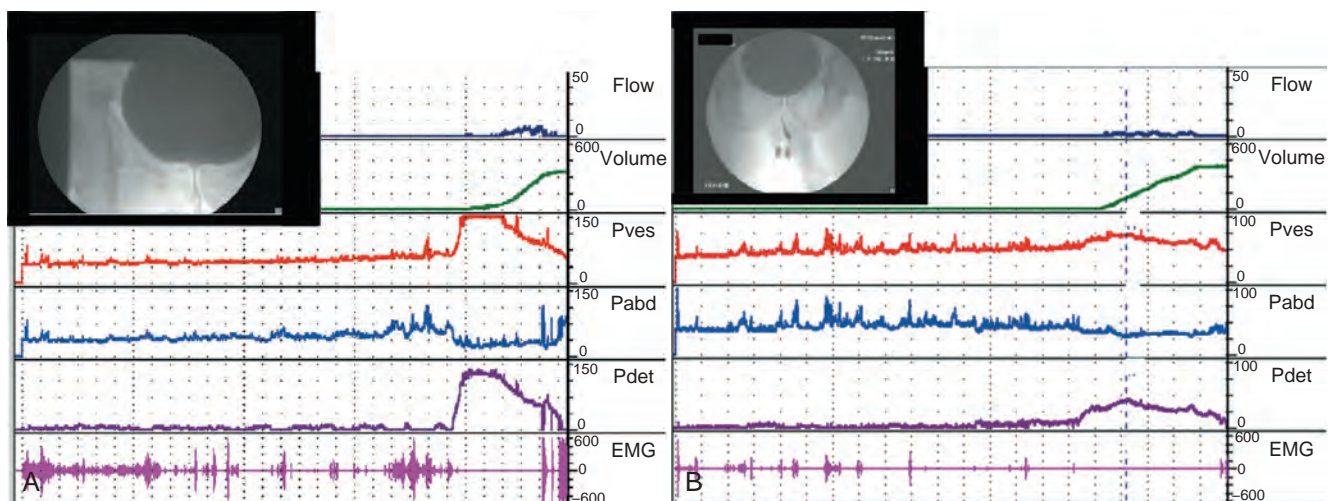

Figure 73-20. Primary bladder neck obstruction (dysfunction). A, Type 1: High-pressure, low-flow voiding in a 45-year-old man with severe lower urinary tract symptoms (LUTS), including frequency, urgency, and decreased force of stream. Image is taken during voiding. Note the incompletely opened bladder neck. B, Type 2: Normal-pressure, low-flow voiding in a 35-year-old man with LUTS similar to those in the patient in A. There is also an incompletely open bladder neck during voiding. The much lower voiding pressures compared to those in A should still be enough to empty normally, though there may be a component of impaired contractility because the bladder was unable to compensate for the increased resistance at the bladder neck. (From Nitti VW. Primary bladder neck obstruction in men and women. *Rev Urol* 2005;7[Suppl. 8]:S12-7.)

bladder compliance to not be a reflection of the measured pressure because one of the upper urinary tracts now absorbs the pressure. If reflux is not diagnosed, reduced bladder compliance can be missed. VUDS is very useful in situations in which reflux is suspected or if hydronephrosis is present (Fig. 73-21).

The AUA/SUFU Urodynamic Guideline supports the use of VUDS in young men and women without an obvious anatomic cause of obstruction, because it can differentiate between functional causes of obstruction such as primary bladder neck obstruction and dysfunctional voiding (Winters et al, 2012). They further state that VUDS is the only diagnostic tool that can document pressure/flow parameters and localize functional bladder neck obstruction. However, the panel recognized that studies have not been performed comparing treatment outcomes of men and women diagnosed with VUDS versus those who had treatment but no VUDS.

VUDS is an important aid in diagnosing neuropathic voiding dysfunction as well as other conditions that may cause elevated

storage pressures. In cases in which VUR occurs, the volume and pressure at which it starts can be documented. In fact, in cases of impaired compliance, in which there is compensation by the pop-off mechanism of VUR, the impaired compliance might not be identified unless the reflux is also recognized by fluoroscopy. In addition, an accurate DLPP can be obtained in cases in which it would otherwise be impossible to position a patient to observe leakage (e.g., some tetraplegics). Furthermore, in cases of possible internal sphincter dyssynergia (often found in conjunction with external sphincter dyssynergia), VUDS is the only way to make the diagnosis and can dramatically change treatment (Fig. 73-22). The EAU Guidelines state that VUDS is the gold standard for invasive UDS in patients with NLUTD (Pannek et al, 2013). If VUDS is not available, a filling CMG plus pressure-flow study should be done. The AUA/SUFU Urodynamics Guideline also recognizes the value of VUDS in patients with NLUTD (Winters et al, 2012). The panel concluded that adding simultaneous fluoroscopy during CMG and

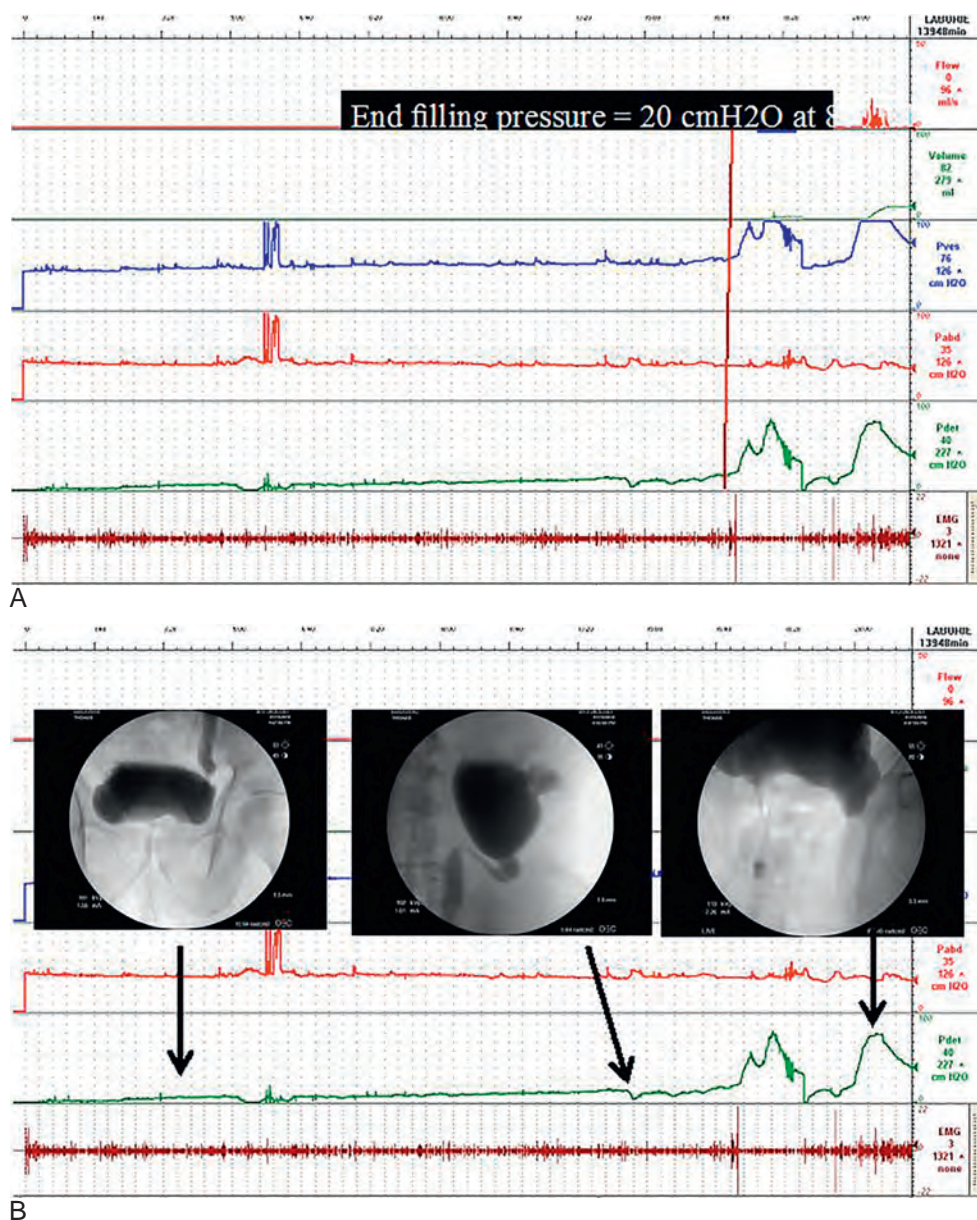

Figure 73-21. A, Urodynamics study of a 75-year-old man with elevated postvoid residual and left hydronephrosis. The end filling pressure is 20 cm H₂O indicating “safe” storage pressures. B, Video-urodynamics shows early reflux at low bladder pressures and significant reflux as bladder filling continues. This represents a “pop-off” mechanism, and the true “functional” bladder compliance is actually significantly more impaired than would be determined by bladder pressure alone.

Figure 73-22. Video-urodynamics evaluation of a man with cervical spine injury with neuropathic voiding dysfunction with incontinence and incomplete emptying. The urodynamics tracing clearly shows detrusor overactivity with detrusor external sphincter dyssynergia (DESD) (increased electromyography [EMG] activity with involuntary contraction). However, it is only with the fluoroscopic view of the bladder outlet during an involuntary contraction that DESD is diagnosed (the bladder neck remains relatively closed).

pressure-flow study provided additional worthwhile diagnostic information beyond what either study alone could provide. However, they also warn that because radiation exposure is additive, studies should be done in a manner that provides the desired clinical information at the lowest possible radiation dose to the patient.

Although VUDS can be helpful in many cases, it is not readily available to all physicians. VUDS is the procedure of choice for documenting bladder neck dysfunction in men and women. In addition, patients at high risk for complicated voiding dysfunction, such as those with known or suspected NLUTD, unexplained urinary retention in women, prior radical pelvic surgery, urinary diversion, prerenal or postrenal transplant status, or prior pelvic radiation, should be considered for referral to a center with VUDS capabilities if a complete and accurate diagnosis cannot otherwise be obtained (Scarpero et al, 2009).

KEY POINT: VIDEO-URODYNAMICS IN NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

- VUDS is usually considered the gold standard for invasive UDS in patients with NLUTD.

AMBULATORY URODYNAMICS

Ambulatory urodynamic studies are defined as a functional test of the LUT, using natural filling, and reproducing the subject's daily activities (Abrams et al, 2002). The development of natural and slow filling urodynamic studies was initially undertaken in the investigation of patients with NLUTD by Comarr (1957) using diuresis-induced natural filling. He demonstrated an increase in bladder capacity and decreases in bladder pressures during natural filling when compared to retrograde filling CMG. Similar investigations of patients with spinal cord injury (SCI) by Tsiju and coworkers (1960) demonstrated increased phasic DO associated with incontinence during natural filling. Today it is a well-established method for investigating LUT function under the conditions of normal daily activities. Ambulatory UDS has its greatest value in patients in whom conventional UDS is not suitable or is unable to reproduce symptoms in question.

In 2000, the ICS published guidelines for the performance of ambulatory UDS (van Waalwijk van Doorn et al, 2000). Before the

investigation, patients receive detailed information describing the test and the necessary preparation. Patients are instructed on how to accurately record symptoms and how to identify catheter displacement and hardware failure. A sample diary is given to record all relevant events so that UDS findings can be correlated with symptoms. Most systems employ microtip transducer catheters, which allow the most mobility. These are placed transurethral to record bladder pressure and transrectally to record Pabd. These catheters are firmly secured to the patient and are connected to a portable recording device. Some systems contain a third channel, which can be used for measuring urinary leakage objectively using an absorbent electronic (capacitance change) nappy pad (Robertson and Neil, 1998). This allows accurate data to be obtained on the relationship of urinary leakage to detrusor activity. Home uroflowmetry units also are available. After the completion of testing, ambulatory UDS tracings are analyzed, which can be a time-consuming process depending on the length of the study. This must be done with great care and frequent quality checks to make sure that urethral and abdominal catheters are properly transducing pressure (e.g., using cough tests). In addition, the reader must be able to identify physiologic artifacts (after contractions and aberrant rectal pressures) and technical artifacts (movement or variation in pressure and lack of balance in the transducer lines), which could have an impact on the interpretation of the study. The ambulatory study should be designed to reproduce symptoms. For example, if the patient complains of stress incontinence, a standard protocol of exercises can be performed and recorded (e.g., jumping up and down, squatting, coughing).

CLINICAL UTILITY OF AMBULATORY URODYNAMICS

Ambulatory UDS is performed in an effort to capture more realistic or more physiologic observations, especially of incontinence episodes (Hosker et al, 2009). It attempts to increase sensitivity by providing a longer time for DO (and other abnormalities) to manifest. Practically speaking, ambulatory UDS is most useful when standard UDS is inconclusive and diagnosis and, more importantly, treatment are uncertain. Ambulatory UDS has been most commonly used to diagnose the cause of urinary incontinence but also has been applied to the diagnosis of male BOO and NLUTD. However, ambulatory UDS is not without limitations. Aside from obvious potential technical challenges, Rosier and associates (2013) noted that there are no published data on the reproducibility or test-retest differences of ambulatory UDS studies nor is there any report that evaluates the investigator dependence on the post-test analysis of recorded data. Further, a Cochrane review looking for randomized or quasi-randomized trials did not show adequate evidence that one technique of UDS was superior to the other (Glazer and Lapitan, 2012).

It has been shown that ambulatory monitoring detects more actual incontinence in symptomatically incontinent patients than retrograde filling CMG (Cassidenti and Ostergard, 1999). Dokmeci and colleagues (2010) prospectively classify incontinent women into three groups (urgency incontinence, stress incontinence, and mixed incontinence) using the UDI-6 questionnaire. Both conventional UDS and ambulatory UDS were prospectively performed. Overall, ambulatory UDS findings matched the classification in 77.3% of women, compared to 6.8% using conventional UDS ($P = .001$). The authors suggested that conventional UDS has a higher false-negative rate than conventional UDS. It is important to note that during this study the conventional UDS were performed with the patients in the supine position (and then the seated position), but not in the standing position, which is often recommended. Another limitation was the measure of incontinence during ambulatory UDS and was based only on the patient-controlled event marker. This introduces a bias, and thus the results must be interpreted cautiously.

Several studies have shown ambulatory UDS to be more sensitive than conventional CMG for the diagnosis of DO (Robertson et al, 1994; Heslington and Hilton, 1996). Radley and associates (2001)

found that ambulatory monitoring revealed DO in 70 of 106 women with symptoms suggestive of DO (twice as many as conventional CMG with provocation by hand washing), and that it detected DO incontinence in 40 of the 70. The observation of DO incontinence was correlated with symptom severity, but it was not clear how many women reporting urgency incontinence showed DO incontinence. Thus the sensitivity is unknown. The finding of higher rates (and sensitivity) of DO on ambulatory monitoring must be weighed against the fact that ambulatory UDS has also found higher rates of DO in asymptomatic volunteers. The rates of DO found in asymptomatic females were noted as high as 69% versus 18% for conventional CMG (van Waalwijk van Doorn et al, 1996) and 38% versus 17% in asymptomatic men and women (Robertson et al, 1994). Thus some degree of DO may be normal in the setting of a urethral catheter for a prolonged period, making some sort of standardization important.

In a review of 422 female ambulatory UDS studies over a 12-year period, Patravali (2007) argued for the value of the study. It was seen that 85% of patients reporting urinary incontinence showed detectable leakage with a diagnosable mechanism on ambulatory study; in 77% of 74 women with a normal CMG, ambulatory UDS diagnosed the cause of incontinence and provided “clear added value.” DO was a component in 42 of these 57 patients (76%). What is not known is exactly what is meant by “clear added value” and how treatment was affected. In a smaller study of 25 patients, Pannek and Pieper (2008) had similar findings but a more useful interpretation of those findings. They found that ambulatory UDS was helpful (vs. conventional UDS) in diagnosing LUTD in 72% of the evaluable examinations. However, 24% of the studies done were not evaluable owing to technical problems or catheter dislocation. Thus ambulatory UDS was clinically useful in only 48% of the patients who underwent this examination. When a diagnosis was made on ambulatory UDS, successful treatment was established in 42% of the patients. However, when ambulatory UDS was not helpful and patients were treated based on clinical symptoms, 33.3% were treated successfully. Gorton and Stanton (2000) also looked at the effect of ambulatory UDS on clinical management. In a retrospective review of 71 women there were technical difficulties in 42% of the studies, with 2 being noninterpretable. DO was found in 45% and nearly all were treated with medication. Among the remainder without DO, fewer received medication. However, fewer than half of those who received medication improved. The authors concluded that ambulatory UDS was not very helpful in deciding on management.

Ambulatory UDS has been used for the diagnosis of obstruction in men with LUTS and inconclusive (borderline or nondiagnostic) conventional pressure-flow studies. Rosario and coworkers (1999) reclassified 24% of such patients as either obstructed or nonobstructed. However, Robertson and colleagues (1996) found no difference in the classification of patients with ambulatory versus conventional pressure-flow studies.

It has been demonstrated that storage pressures in patients with NLUTD (and chronic obstruction) are lower on ambulatory, natural fill UDS than on conventional CMG (Webb et al, 1989, 1991, 1992). Patients with poor compliance (high filling pressures) and hydronephrosis on conventional CMG were found to have normal compliance, but significant phasic neurogenic DO on ambulatory monitoring. It has been suggested that phasic neurogenic DO and not impaired compliance may lead to upper tract deterioration in these patients. Although this may be true, it needs to be proved in a series of patients followed over time; for now, based on the available evidence, it must still be concluded that significantly impaired compliance on conventional CMG is a risk factor for upper tract damage.

Martens and associates (2010) looked at 27 patients with SCI and symptoms suggestive of neurogenic DO. These patients underwent both conventional and ambulatory UDS (for 6 hours). It was reported that a greater percentage of patients were found to have neurogenic DO on the ambulatory study (92% vs. 69%, $P = .031$), but there was no difference in the bladder pressure during the IDC. Comparing each method to the “clinical diagnosis of DO” ambula-

tory UDS had a sensitivity to detect neurogenic DO of 85% and conventional UDS had a sensitivity of 75%, but this was not significant ($P = .375$). The authors also found that the interindividual agreement to diagnose neurogenic DO was higher for the conventional UDS compared to the ambulatory UDS. They did look at how the studies altered management recommendations and concluded that although ambulatory UDS did not need to be used as a standard tool for risk assessment in patients with SCI, ambulatory UDS remain indicated if conventional UDS are not conclusive for treatment decisions.

VUDS are often considered the gold standard for the evaluation of patients with NLUTD (Pannek et al, 2013), but most studies in this population have compared ambulatory UDS to conventional UDS, but not VUDS. Virseda-Chamorro and associates (2014) compared ambulatory UDS (with a single natural fill cycle) in 69 patients with SCI. The patients were grouped by findings noted on fluoroscopy, including having an open bladder neck at rest, DESD, and VUR (in this population representing 25%, 64%, and 6% of patients, respectively); they found no association with ambulatory UDS findings. The only statistically significant finding was patients with an open bladder neck on VUDS had a higher percentage of neurogenic DO (67%) on ambulatory UDS compared to patients whose bladder neck was closed at rest (35%) ($P = .025$). This study also found lack of agreement in most other filling parameters when comparing other VUDS parameters to ambulatory UDS parameters. The cytometric capacity on ambulatory UDS (275 mL) aligned more closely with frequency volume chart bladder capacity (296 mL). VUD capacity was noted to be higher (416 mL). It is not clear that this information alters management or affecting outcomes.

When considering the use of ambulatory UDS in the clinical evaluation of NLUTD the possibility of autonomic dysreflexia deserves mention (Cameron, 2011). It was suggested that prolonged periods of catheterization and irritation from multiple catheters could be an issue, but the data about frequency of autonomic dysreflexia episodes and the ability to recognize and adequately manage autonomic dysreflexia has not been systematically evaluated.

Attempts have been made to modify the ambulatory urodynamic equipment needed and have shown some promising results in identifying neurogenic DO (Kim et al, 2010; Kim and Song, 2012). Aside from technical advances and accuracy, cost, convenience and patient experience must also be considered moving forward.

In conclusion, ambulatory UDS may be useful in a select group of patients in whom conventional UDS is nondiagnostic and the information provided would affect treatment, counseling, or follow-up. Ambulatory UDS and its interpretation are time-consuming and technically challenging. The data obtained for ambulatory UDS studies must be weighed against the fact that for many findings, standards—both normal and abnormal—have not been established. More data are needed on the reproducibility of ambulatory UDS. The impact that ambulatory UDS has on altering management and changing both patient-reported and objective outcomes should be investigated across varied patient populations.

KEY POINT: AMBULATORY URODYNAMICS

- Ambulatory UDS may be useful in a select group of patients in whom conventional UDS is nondiagnostic and the information provided would affect treatment, counseling, or follow-up.

CLINICAL APPLICATIONS OF URODYNAMIC STUDIES: EVIDENCE-BASED REVIEW

Thus far in this chapter we have described the technical aspects of UDS and general indications for use. In this final section, we will

provide an evidence-based review of UDS for different common clinical applications. In many situations there is not enough evidence in the literature to conclude how useful UDS is for a particular case, and thus its use should be based on a clinical impression. Nevertheless, there are some instances and indications in which the evidence is strong enough to provide guidance as to how useful UDS will be. In cases in which recommendations are made, these are based on the Oxford system: Grade A recommendation usually depends on consistent level 1 evidence and often means that the recommendation is effectively mandatory and placed within a clinical care pathway. Grade B recommendation usually depends on consistent level 2 and or 3 evidence studies, or “majority evidence” from randomized controlled trials. Grade C recommendation usually depends on level 4 evidence studies or majority evidence from level 2/3 studies or from expert opinion. We will specifically address four areas in which UDS is commonly used for evaluation and enough evidence exists to make valid conclusions or recommendations: women with SUI, men and women with LUTS, and NLUTD.

EVALUATION OF WOMEN WITH STRESS INCONTINENCE

For the last decade, it generally has been thought that **for women with pure SUI without urgency symptoms who empty normally and demonstrated SUI on physical examination, UDS will not provide much useful information.** For example, in the Stress Incontinence Surgical Treatment Efficacy (SISTER) trial, a randomized trial comparing the efficacy of the Burch procedure versus the pubovaginal sling in 655 *selected* women with pure or predominant SUI and no obvious emptying problems, UDS, including ALPP and presence of DO, added little to help determine surgical outcomes with respect to efficacy (Nager et al, 2008) or postoperative voiding dysfunction (Lemack et al, 2008). In 2006, in the United Kingdom, the National Institute of Health and Clinical Excellence issued guidelines that UDS was recommended before surgery for urinary incontinence only if there is a clinical suspicion of DO, if there has been previous surgery for stress incontinence or anterior compartment prolapse, or if there are symptoms suggestive of voiding dysfunction. In the past several years there have been two randomized controlled trials that were designed to answer the question of how useful UDS is in the evaluation of women with straightforward SUI.

The Value of Urodynamic Evaluation Trial (ValUE) was a multicenter, randomized noninferiority trial involving women with uncomplicated, stress-predominant urinary incontinence who were planning to undergo surgery to determine whether outcomes at 1 year among women who underwent only an office evaluation were inferior to those among women who also underwent preoperative urodynamic studies (Nager et al, 2012). The study included a select group of women who had pure or stress-predominant SUI based on a validated questionnaire, a PVR less than 150 mL, a negative urinalysis or urine culture, or urethral mobility with a positive provocative stress test. Women with previous surgery for incontinence, a history of pelvic irradiation, pelvic surgery within the previous 3 months, and significant anterior or apical pelvic organ prolapse were excluded. A total of 630 women were equally randomized to office evaluation plus UDS versus office evaluation alone. The primary outcome was surgical treatment success measured as a reduction in the Urogenital Distress Inventory score from baseline to 12 months of 70% or more and a Patient Global Impression of Improvement response of “very much better” or “much better” at 12 months. The proportion in which treatment was successful was 76.9% in the urodynamic-testing group versus 77.2% in the evaluation-only group (difference, −0.3 percentage points; 95% confidence interval [CI] −7.5 to 6.9), which was consistent with noninferiority. The authors did note that based on UDS, 18 women had the type of surgery changed from transobturator to retropubic midurethral sling (12) or from retropubic to transobturator sling (6). It is not clear if these changes affected outcomes. The authors concluded that for women with uncomplicated, demonstrable SUI,

preoperative office evaluation alone was not inferior to evaluation with urodynamic testing for outcomes at 1 year. In a follow-up study (Zimmern et al, 2014), the authors found that for patients who underwent UDS, physician confidence for the diagnosis of ISD, overactive bladder wet and dry (presumably DO), and voiding phase dysfunction, but not SUI, increased. However, this did not correlate with treatment success.

In another study to investigate the value of UDS before SUI surgery, van Leijssen and associates (2013) conducted a multicenter diagnostic cohort study with an embedded noninferiority randomized controlled trial in 6 academic and 24 nonacademic Dutch hospitals. All women in the trial had SUI or stress predominant mixed incontinence and underwent UDS. Those who had UDS that were discordant with clinical assessment (SUI was not confirmed, DO, weak flow, elevated PVR, small cystometric maximum capacity, or a reduced bladder sensation), were then randomly allocated to receive either immediate surgery or individually tailored therapy based on UDS. Possible treatment options included anticholinergics for DO, prolonged pelvic floor exercises or bladder training in cases of dysfunctional voiding, a pessary, expectant management, intravesical botulinum toxin injections, or pretibial nerve stimulation at the physician's discretion. Of the 578 included women, 268 women (46%) had urodynamic findings that were discordant with clinical history and physical examination. Consent for randomization was obtained from 126. Of the patients randomized to individualized treatment, 57 of 62 received surgery as the initial treatment. The mean improvement on the Urogenital Distress Inventory UI subscale was 39 points (± 25) in the group who received individually tailored treatment compared with 44 points (± 24) in the group receiving immediate surgery. The difference in mean improvement was 5 points in favor of the group receiving immediate surgery, confirming noninferiority for either one of the strategies. Subjective cure as measured with the Urogenital Distress Inventory and objective cure as measured with the stress test and bladder diary were not different between the two arms. In the surgery group, subjective cure was 43 of 58 (74%) and in the individual treated group was 42 of 56 (75%) (relative risk [RR] 0.99, 95% CI 0.80 to 1.23). Objectively cured were 37 of 38 women (97%) in the surgery group and 33 of 34 women (97%) in the individual treated group (RR 1.00, 95% CI 0.93 to 1.09). The authors concluded that in women with uncomplicated SUI, an immediate midurethral sling operation is not inferior to individually tailored treatment based on urodynamic findings.

These two well-done studies suggest that UDS is not essential before surgical treatment of stress-predominant urinary incontinence in women when SUI is seen clinically. However, many women with SUI who are considering surgical correction have mixed symptoms or emptying difficulties and it is here that UDS probably has its most significant role for female SUI. In addition, previous studies found significant variation of the predictive value of symptoms in identifying the three UDS observations of urodynamic SUI, DOI, and mixed urinary incontinence (Harvey and Versi, 2001; Homma, 2002; Agur et al, 2009). This variation is probably explained by the nonhomogeneous patient populations and an inconsistency in the clinical and the UDS diagnosis among the studies.

We believe that UDS does have a valuable and definitive role in the preoperative evaluation of patients with SUI and significant urgency symptoms. In fact, several studies have shown excellent cure rates for both stress and urgency symptoms in women with urodynamic SUI and a normal CMG (no DO) for pubovaginal sling (Chou et al, 2003), Burch procedure (Osman, 2003) and tension-free vaginal tape (Rezpour and Ulmsten, 2001). It should be noted that the trials that have shown no difference in success of treatment with or without DO were primarily done in patients with stress-predominant SUI. The presence or absence of DO in women with more significant urgency symptoms may play a more significant role in predicting outcomes.

Based on a thorough review of the literature the AUA Urodynamics Guideline Panel has made the following statements (Winters et al, 2012):

1. "Clinicians who are making the diagnosis of urodynamic stress incontinence should assess urethral function. (Recommendation; Evidence Strength: Grade C)." The committee recommends that if UDS is performed, an assessment of urethral function (e.g., ALPP or MUCP) should be performed. This seems reasonable as an ALPP may for some surgeons affect the type of surgery performed, because inferior outcomes have been found for some procedures in patients with low ALPP and/or MUCP.
2. "Surgeons considering invasive therapy in patients with SUI should assess PVR urine volume. (Expert Opinion)." An elevated PVR may prompt a change in treatment for additional testing such as UDS.
3. "Clinicians may perform multichannel UDS in patients with both symptoms and physical findings of SUI who are considering invasive, potentially morbid, or irreversible treatments. (Option; Evidence Strength: Grade C)." This statement allows the clinician to make a decision on the selective use of preoperative UDS based on patient symptoms, how the study will influence choice of surgery, and the degree of confidence that the surgeon has in the diagnosis.
4. "Clinicians should perform repeat stress testing with the urethral catheter removed in patients suspected of having SUI who do not demonstrate this finding with the catheter in place during urodynamic testing. (Recommendation; Evidence Strength: Grade C)." It is well established that some women will not demonstrate SUI with a catheter in place. This maneuver is especially important in a woman who does not demonstrate SUI on physical examination.
5. "In women with high-grade pelvic organ prolapse but without the symptom of SUI, clinicians should perform stress testing with reduction of the prolapse. Multichannel UDS with prolapse reduction may be used to assess for occult stress incontinence and detrusor dysfunction in these women with associated LUTS. (Option; Evidence Strength: Grade C)." Prolapse reduction is extremely important if the demonstration of occult SUI on UDS will influence the type of prolapse surgery performed (i.e., a simultaneous anti-incontinence with prolapse repair).

The EAU Guidelines on UDS are not specific to SUI in women, but, nevertheless, make a number of practical recommendations, which are consistent with the AUA Guideline (Lucas et al, 2013).

Clinicians carrying out UDS in patients with urinary incontinence should:

1. Ensure that the test replicates the patient's symptoms (grade C).
2. Interpret results in context of the clinical problem (grade C).
3. Advise patients that the results of UDS may be useful in discussing treatment options, although there is limited evidence that performing UDS will alter the outcome of treatment for urinary incontinence (grade C).
4. Do not routinely carry out UDS when offering conservative treatment for urinary incontinence (grade B).
5. Perform UDS if the findings may change the choice of invasive treatment (grade B).
6. Do not routinely carry out urethral pressure profilometry (grade C).

Both AUA and EAU Guidelines give the clinician the discretion to perform UDS before surgery, based on the individual patient, clinical scenario, and whether UDS will ultimately affect the choice of treatment (the latter varies based on the individual clinician). It is our practice that for cases of straightforward SUI with no or minimal urgency symptoms and with normal bladder emptying, it seems reasonable to forego UDS evaluation because it does not affect our choice of treatment or the outcomes of that treatment. We find UDS most useful in women who have significant urgency and/or urgency incontinence, bladder emptying problems, prior stress incontinence surgery, uncertain diagnosis or inability to demonstrate SUI on physical examination, history of pelvic radiation, neurologic disease, and very severe symptoms (total or near total). We also find UDS useful in elderly women, because we do not believe that the existing literature has investigated this group sufficiently to suggest that UDS is not useful.

EVALUATION OF MEN AND WOMEN WITH LOWER URINARY TRACT SYMPTOMS

The cause of LUTS in men and women is multifactorial, comprising at least four conditions: (1) BOO, (2) DU, (3) DO, and (4) sensory urgency (Blaivas, 1988). Often storage symptoms of frequency and urgency accompany voiding symptoms of decreased force of stream and hesitancy. Urgency incontinence also can occur as a result of DO with or without BOO. LUTS are common among men of 50 years and over. It has been established that coexistence of BOO and DO in men increases with age and with the degree of BOO (Vesely et al, 2003; Oelke et al, 2008). In such cases, UDS can be helpful to establish the underlying bladder and/or bladder outlet abnormality.

Noninvasive testing such as PVR and uroflowmetry can be helpful in the evaluation of men and women with LUTS and also may prompt further invasive UDS testing. The AUA Urodynamics Guideline (Winters et al, 2012) states that, "Clinicians may perform PVR in patients with LUTS as a safety measure to rule out significant urinary retention both initially and during follow-up (Clinical Principle)." Although it is true that PVR cannot differentiate between obstruction and nonobstructive conditions (e.g., DU) and that there is no agreed-upon definition of exactly what volume constitutes an elevated PVR, most urologists would agree with this statement. The Guideline also states that uroflow may be used by clinicians in the initial and ongoing evaluation of male patients with LUTS that suggest an abnormality of voiding/emptying (recommendation; evidence strength: grade C). Like PVR, an abnormal uroflow cannot differentiate between obstruction and DU; however, it can be helpful in instituting or not instituting certain therapies or in prompting further testing.

The question of how much help UDS is in the evaluation and treatment of male LUTS has been debated for years. How necessary is a diagnosis of BOO before transurethral prostate resection, for example? The answer depends on how comfortable the clinician is in making a diagnosis and treating with less invasive and less definitive testing. Few would argue that, to institute an α -receptor blocker for the treatment of LUTS in a man with relatively normal bladder emptying, UDS is not required. However, as the scenario becomes more complex and the treatment more invasive and potentially morbid, a precise diagnosis will be helpful in many cases. Often it is ultimately up to the clinician to decide how much information is useful or necessary to make a treatment decision and properly counsel patients.

It is well documented that in men with BOO, surgery such as TURP (by any means) reduces obstruction and relieves symptoms. However, storage symptoms such as urgency frequency and urgency incontinence will persist in approximately one third of cases. It has been shown that when storage symptoms are associated with DO and BOO, UDS can help predict resolution of those symptoms. In such a scenario, storage symptoms have a higher likelihood of resolving with intervention (e.g., TURP) when DO occurs as a single terminal IDC rather than continuous or sporadic IDCs (Kageyama et al, 2000). Such information can be quite valuable when counseling patients. For example, given the same UDS presentation of BOO plus continuous IDCs, a patient primarily concerned with the inability to empty may opt for surgery whereas a patient who is primarily concerned about overactive bladder symptoms may not.

As for the utility of UDS before surgical treatment or no treatment of LUTS thought to be secondary to BPH, the literature is mixed, with several studies supporting its necessity (Javle et al, 1998; Rodrigues et al, 2001; Porru et al, 2002; Thomas et al, 2004) and others concluding that UDS is not necessary (Pannek et al, 1998; Kanik et al, 2004) or necessary only in inconclusive cases (Ignjatovic, 1997). Other reviews (Abrams et al, 2001; Homma, 2001; Clemens, 2003; Brucker and Jaffe, 2009) suggest that UDS has some, but not strong, predictive value for the outcome of treatment. Another review, by Bhargava and coworkers (2004), concluded that conventional urodynamic studies are useful in providing preoperative information about detrusor function and to exclude

patients less likely to benefit from prostate surgery. Despite this, some regard the need for performing urodynamic evaluation routinely, before TURP, as still controversial. This led the experts at the 6th International Consultation on New Developments in Prostate Cancer and Diseases to conclude that almost all evidence for the advantages of UDS before invasive therapy for benign prostatic obstruction (BPO) is level 3 (good-quality retrospective case-control studies or case series), and the quantity of evidence allows a grade B recommendation (Abrams et al, 2006). In a similar statement, the AUA Urodynamics Guideline (Winters et al, 2012) states that, "Clinicians should perform pressure-flow studies in men when it is important to determine if urodynamic obstruction is present in men with LUTS, particularly when invasive, potentially morbid, or irreversible treatments are considered (Standard; Evidence Strength: Grade B)."

Most of the time when BOO is treated it is done because of symptoms. However, asymptomatic BOO, if not relieved in time, may lead to progression of the disease and affect organ function. For many years attention was paid only to the backpressure effects of obstruction on the kidneys (from high voiding pressures and/or impaired compliance). However, it is now known that BOO affects bladder function, leading to structural changes. Because the changes may eventually become irreversible, some would argue that management should be directed toward early relief of significant obstruction (Flanigan et al, 1998; Lu et al, 2000; Brierly et al, 2003). However, at this time, a critical level of obstruction (e.g., based on the BOOI) has not been defined. There are no evidence-based studies to suggest when surgical relief is indicated to prevent bladder decompensation. Many papers have shown, however, that if there is no evidence of obstruction on pressure-flow studies, the results of surgical relief are not as good (Porru et al, 2002; Thomas, 2004). Significantly impaired compliance remains the only absolute urodynamic indication for treating BOO.

At times it may be important to diagnose DO or more importantly impaired compliance that is associated with LUTS. In addition to BOO, conditions such as radiation cystitis and certain inflammatory diseases (e.g., tuberculosis) can cause impaired compliance. Impaired compliance, however, can be diagnosed only by CMG. In such cases, the diagnosis of impaired compliance can result in the institution of therapy independent of symptoms. Thus, in cases in which impaired compliance is suspected, we recommend UDS testing. This is consistent with the following AUA Guidelines statements:

1. "Clinicians may perform multichannel filling cystometry when it is important to determine if altered compliance, DO or other urodynamic abnormalities are present (or not) in patients with urgency incontinence in whom invasive, potentially morbid, or irreversible treatments are considered. (Option; Evidence Strength: Grade C)"
2. "Clinicians may perform multi-channel filling cystometry when it is important to determine if DO or other abnormalities of bladder filling/urine storage are present in patients with LUTS, particularly when invasive, potentially morbid, or irreversible treatments are considered is consistent with the available information (Expert Opinion)."

As in men, women with emptying problems (poor emptying and/or voiding symptoms) may benefit from UDS with voiding pressure-flow studies. This can help differentiate obstruction from impaired contractility. UDS is particularly helpful when the cause of obstruction is not obvious. Anatomic obstruction (high-grade prolapse, incomplete emptying after incontinence surgery, urethral mass) is usually obvious. However, functional obstruction such as dysfunctional voiding or primary bladder neck obstruction is not obvious on physical examination or endoscopy and requires evaluation during voiding. We agree with the AUA Urodynamics Guideline statement (Winters et al, 2012) that "Clinicians may perform pressure-flow studies in women when it is important to determine if obstruction is present. (Recommendation; Evidence Quality: Grade C)." We find VUDS to be particularly helpful because it can diagnosis and localize obstruction (see earlier section on Video-Urodynamics).

EVALUATION OF NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

NLUTD usually manifests clinically as incontinence and/or inability to empty the bladder. Incontinence may be of bladder origin (DO or impaired compliance) or sphincter origin. Poor emptying also can be of bladder origin (DU or acontractile bladder) or sphincter origin (dyssynergia). In addition to symptomatic presentation, NLUTD can present as upper urinary tract decompensation with hydroureteronephrosis and renal insufficiency without bothersome symptoms. The goal of management in these patients is to prevent upper tract decompensation and relieve symptoms. A specific understanding of the pathophysiology of the condition in each individual is essential for the correct choice of therapy (Stöhrer, 1990; Stöhrer et al, 1994; Rivas and Chancellor, 1995). UDS probably has its most important role in the evaluation and management of patients with neurogenic voiding dysfunction.

The aims of therapy for NLUTD are to achieve physiologic filling (and if possible voiding) conditions as well as to control symptoms and create a management situation acceptable to the patient in daily life. Much of the evidence base for management of the LUT in the neurogenic patient consists of level 3 or lower evidence. This is primarily because of the potential negative consequences of untreated neurogenic dysfunction. Thus, randomized controlled trials are thought by many to be dangerous and unethical. Because prolonged periods of elevated Pdet during bladder filling or abnormally prolonged elevated pressures during voiding have been found to put the upper urinary tract at risk (McGuire et al, 1996; Kurzrock and Polse, 1998; Tanaka et al, 1999), the primary aim of therapy in patients with such problems is conversion to a low-pressure bladder during filling, even if this leads to incomplete emptying and the need to supplement emptying with catheterization. Adequate therapy depends on whether the detrusor is overactive or has reduced compliance, and only UDS can answer those questions unequivocally. In addition to the prevention and amelioration of upper and lower urinary tract abnormalities/decompensation, timely and adequate diagnosis of DO and impaired compliance is thought to be of paramount importance for the patient's quality of life (Stöhrer, 1990; Stöhrer et al, 1994; Bomalaski et al, 1995; Cardenas et al, 1995). UDS is also essential for assessing the response to treatment and following any sequelae of the disease and its management (Hosker et al, 2009).

Not all NLUTD requires UDS before observation or treatment. Conditions in which high storage pressures are not suspected (e.g., urgency incontinence after a stroke or women with multiple sclerosis with a low PVR) often can be managed initially without UDS. But in cases in which the neurologic condition/lesion can cause potentially harmful storage situations (spinal cord injury, myelomeningocele), UDS is essential both before treatment and also in ongoing follow-up of the condition and to monitor the response to treatment. In the middle are situations in which UDS can be helpful in guiding management (e.g., men with possible BPO and Parkinson disease or multiple sclerosis). The AUA Guidelines contains the following five very important and practical statements regarding UDS in NLUTD:

1. Clinicians should perform PVR assessment, either as part of complete urodynamic study or separately, during the initial urologic evaluation of patients with relevant neurologic conditions (e.g., spinal cord injury, myelomeningocele), and as part of ongoing follow-up when appropriate (Standard; Evidence Strength: Grade B).
2. Clinicians should perform a complex CMG during initial urologic evaluation of patients with relevant neurologic conditions with or without symptoms and as part of ongoing follow-up when appropriate. In patients with other neurologic diseases, physicians may consider CMG as an option in the urologic evaluation of patients with LUTS (Recommendation; Evidence Strength: Grade C).
3. Clinicians should perform pressure-flow analysis in patients with relevant neurologic disease with or without symptoms or in patients with other neurologic disease and elevated PVR

or urinary symptoms (Recommendation; Evidence Strength: Grade C).

4. When available, clinicians may perform VUDS in patients with relevant neurologic disease at risk for NLUTD or in patients with other neurologic disease and elevated PVR or urinary symptoms (Recommendation; Evidence Strength: Grade C).
5. Clinicians should perform EMG in combination with CMG with or without pressure-flow studies in patients with relevant neurologic disease at risk for NLUTD or in patients with other neurologic disease and elevated PVR or urinary symptoms (Recommendation; Evidence Strength: Grade C).

KEY POINTS: URODYNAMICS BEST PRACTICES

- There is mounting evidence that UDS is not essential before surgical treatment of stress-predominant urinary incontinence in women when SUI is seen clinically.
- According to the AUA Guidelines, pressure-flow studies are performed in men when it is important to determine if urodynamic obstruction is present with LUTS, particularly when invasive, potentially morbid, or irreversible treatments are considered.
- As in men, women with emptying problems (poor emptying and/or voiding symptoms) may benefit from UDS with voiding pressure-flow studies. This can help differentiate obstruction from impaired contractility. UDS is particularly helpful when the cause of obstruction is not obvious.
- UDS probably has its most important role in the diagnosis and management of patients with neurogenic voiding dysfunction.

DEFINITION AND CLASSIFICATION OF URINARY INCONTINENCE

Introduction and Overview of the Lower Urinary Tract

The economic, social, and emotional burden of urinary incontinence (UI) profoundly impacts patients' lives, heavily contributes to health care spending, and results in millions of office visits, diagnostic studies, and therapeutic interventions each year. And although the number of visits and procedures related to UI has steadily increased throughout the past several decades, in fact the number of symptomatic yet undiagnosed women remains substantial (Miller et al, 2009). The challenge for urologists is to identify patients with UI appropriately, to decipher the type of UI present, and in some cases to determine the etiology of the condition. In so doing, one can then begin the discussion of treatment alternatives.

The lower urinary tract is composed of the bladder and urethra, supported by a complex system of neural innervation and musculo-fascial support in the lower pelvis. Lower urinary tract symptoms (LUTS), including UI, might develop as a result of anatomic abnormalities in the lower urinary tract that might be at the macroscopic, microscopic, or ultrastructural level. Such abnormalities include functional disturbances in the various components of the LUT (e.g., the urothelium, detrusor musculature, sphincteric unit) or abnormalities of the surrounding structures impacting the ability of the LUT to perform its normal functions. Those normal functions, which principally involve storing urine at low intravesical pressures during the vast majority of times and expelling urine at socially appropriate and convenient times, may indeed be inexorably influenced by a variety of coexisting urologic and nonurologic conditions, demographic/environmental risks, lifestyle choices, and genetic factors.

Signs, Symptoms, and Urodynamic Observations of Urinary Incontinence

When evaluating the LUT it is essential to distinguish between signs, symptoms, and (urodynamic) observations. These distinc-

tions are necessary particularly because symptoms of LUT dysfunction are often nonspecific. That is to say, varying etiologies of LUT dysfunction can result in very similar LUTS. Urinary urgency, for example, can represent underlying overactive bladder (OAB), bladder outlet obstruction (BOO), prolapse, and interstitial cystitis/painful bladder syndrome, as well as other conditions. The extent to which the urologist must go to clarify the etiology varies by condition, invasiveness/risk of the proposed intervention, and, to a certain extent, comfort level of the clinician and patient. Suffice it to say, however, that in many cases, the more definitive the diagnosis, the more effective the proposed treatment strategy will likely be.

A sign of LUT dysfunction is considered as one that is observable by the clinician. For the purpose of LUT dysfunction, this might include, for example, the finding of UI during a supine stress test or the finding of pelvic organ prolapse (POP) in a woman who complains of pelvic pressure. Signs are reproducible and objective.

Symptoms are the subjective complaint, made directly by the patient or reported by a caregiver/family member, of a change in condition from what was previously experienced. By their nature, symptoms are descriptive/experiential, and they reflect noticeable alterations in the patient's perception of their LUT function. Symptoms can be self-reported, or they can be determined through the use of a variety of validated questionnaires, many of which are developed for the sole purpose of attempting to make more objective what is, at its essence, a very subjective report. Symptoms, including incontinence, do not necessarily indicate bother, which is a critical distinction to make, because quality-of-life (QoL) impact is the most common reason to intervene for LUTS. In the absence of QoL change, treatment may not necessarily be indicated.

Observations may be urodynamic or nonurodynamic. Nonurodynamic observations include, for example, information gleaned from patient-completed frequency-volume charts. Urodynamic observations are specific findings made during urodynamic studies that speak to the underlying physiology of lower urinary tract function. Specific guidelines for performing and interpreting urodynamic studies were reviewed (Rosier et al, 2013). Abnormalities of storage (obtained during the cystometrogram portion), voiding (obtained during the pressure flow portion), and post-micturition

TABLE 74-1 Lower Urinary Tract Symptom Definitions

SYMPTOM	DESCRIPTION
Stress urinary incontinence	Complaint of involuntary urinary loss with physical exertion, sneezing/coughing, or other activities raising intra-abdominal pressure
Urgency urinary incontinence	Complaint of involuntary urinary loss associated with sensation of urgency
Mixed urinary incontinence	Complaint of involuntary urinary loss associated with physical exertion/rise in intra-abdominal pressure <i>and also</i> with urgency
Nocturnal enuresis	Complaint of involuntary urine loss during sleep
Continuous urinary incontinence	Complaint of continuous urine loss, day and night
Insensible urinary incontinence	Complaint of urine loss without knowledge of what precipitated the event or when it occurred
Urinary frequency	Complaint that micturition occurs more frequently than deemed normal
Urinary urgency	Complaint of sudden compelling desire to urinate that is difficult to defer
Overactive bladder syndrome	Complaint of urinary urgency, with or without urgency incontinence, typically with frequency and nocturia
Nocturia	Complaint of interruption of sleep resulting from the need to void, where the interruption is preceded and followed by sleep

may be ascertained during the study. Although it is the goal of urodynamics to recreate the symptoms reported by the patient, it is clear that this is neither always feasible, nor perhaps is it necessary. For example, patients with symptoms of pure stress incontinence will often be found to have divergent urodynamic findings—it then becomes the role of the clinician to determine if the urodynamic observations or the patient-reported symptoms are more appropriate to treat (Digesu et al, 2009).

TERMINOLOGY OF LOWER URINARY TRACT SYMPTOMS AND INCONTINENCE

The terminology used to describe LUT dysfunction in women has undergone much iteration during the last several years (Table 74-1). The most recent standardization was developed through a joint effort of the International Continence Society (ICS) and International Urogynecological Association, and includes the terminology that is currently in use (Haylen et al, 2010). Although LUTS are the focus of the present chapter, this important document and its precedent manuscript (Abrams et al, 2002) also include standard terminology used for characterizing prolapse, as well as for performing and interpreting urodynamic investigations. Symptom terminology is typically broken down into abnormalities associated with incontinence, with bladder storage, with bladder sensation, with voiding, and post-micturition disturbances.

Incontinence

UI is the symptomatic complaint regarding the involuntary loss of urine. When assessing UI, it is essential to establish the nature (type), severity, impact on QoL, duration, and frequency with which the incontinence occurs. Validated questionnaires, frequency volume charts, physical examination, and urodynamic testing are all used to evaluate UI symptoms better and to distinguish the type of incontinence present (Fig. 74-1). None of these tools alone is capable of answering these essential questions regarding UI, and their combined use is often helpful in developing treatment strategies.

Stress urinary incontinence (SUI) is the complaint of involuntary loss of urine with physical exertion (i.e., walking, straining, exercise) or with sneezing/coughing or other activities that cause a rise in intra-abdominal pressure. It can be witnessed on exam as involuntary leakage per urethra synchronous with effort, physical exertion, or coughing. This provocative testing is often performed during an office supine stress test. Urodynamic stress incontinence refers to the finding of involuntary urine leakage during filling

Figure 74-1. Overlap between conditions. OAB, overactive bladder; SUI, stress urinary incontinence; UII, urgency urinary incontinence. (From Wein AJ, Rackley, RR. Overactive bladder: a better understanding of pathophysiology, diagnosis and management. J Urol 2006;175:S5–10.)

cystometry associated with an increase in intra-abdominal pressure, and in the absence of a detrusor contraction.

Urgency urinary incontinence (UII) is the complaint of involuntary urine loss associated with urgency. It can be noted on physical exam as the observation of involuntary leakage from the urethra synchronous with the sensation of a sudden, compelling desire to void that is difficult to defer. Whereas urgency incontinence may be diagnosed urodynamically, it need not be present with any specific urodynamic finding such as detrusor overactivity, bladder oversensitivity, or diminished maximum bladder capacity. Detrusor overactivity incontinence, a urodynamic diagnosis, may be present in patients with UII, although it need not be present to establish the diagnosis of UII.

Mixed urinary incontinence (MUI) is the complaint of involuntary urine loss associated with urgency and is also associated with effort, physical exertion, sneezing, or coughing. Mixed symptoms may be urge predominant, stress predominant, or equal. Postural UI is the complaint of involuntary urine loss associated with a change in position (often from sitting/lying down to standing). Nocturnal enuresis is the complaint of involuntary urine loss occurring during sleep and should be distinguished from urgency incontinence, which may occur during the night after being awakened to void but having insufficient time to get to the bathroom to void. Continuous UI is the complaint of continuous urine loss, day and night. This is the type of UI typically seen with fistula of the lower urinary tract involving the vagina (i.e., vesicovaginal and ureterovaginal fistulae). Patients often will have little

to no volitional voids with continuous incontinence. **Insensible UI** is the complaint of urine loss when the patient is unaware of how or precisely when the urine loss occurred. Coital incontinence is the complaint of involuntary loss of urine with sexual intercourse. It may occur with penetration, intromission, and/or during orgasm.

Bladder Storage and Sensation

These symptoms are associated with abnormalities of bladder filling and are not characterized by loss of urine. Symptoms associated with bladder storage include increased daytime frequency, which is the complaint that micturition occurs more frequently than previously deemed normal. In general, eight or more voids within a 24-hour period are considered more than normal, although this finding alone does not necessarily imply bladder dysfunction. **Nocturia** is the complaint of interruption of sleep because of the need to void, where each interruption is preceded and followed by sleep. **Urgency** is the sudden compelling desire to urinate, which is difficult to defer. Urge, by comparison, is a normal bladder sensation that occurs and signals the need to micturate. **OAB syndrome** includes urinary urgency, with or without urgency incontinence, typically accompanied by frequency and nocturia.

Increased bladder sensation implies that the patient experiences the desire to void earlier than previously deemed normal and differs from urgency in that voiding can be postponed. **Reduced bladder sensation**, in contrast, implies that the desire to void comes later than that previously experienced by the patient, despite the fact that the patient is aware that the bladder is filling. **Absent bladder sensation** involves the complaint that both the sensation of bladder filling and the desire to void are absent.

EPIDEMIOLOGY OF URINARY INCONTINENCE IN WOMEN

General Comments

Epidemiologic studies on the topic of UI must be closely scrutinized when determining their relevance. Several factors must be considered when evaluating these types of data. Among the most important of these factors is the definition of UI—indeed altering the definition will result in widely divergent estimates of disease prevalence. In a condition that does not rely on pathologic diagnosis, and one in which the diagnosis may often be made appropriately by history alone, estimates clearly vary widely.

Questionnaires to assess incontinence differ greatly in specificity, length, and complexity, which often results in very different estimates of prevalence. **Questionnaires used in characterizing incontinence differentiate the type of incontinence present, identify the frequency with which it occurs, and address the severity of the condition.** Thus, for example, asking a woman if she has leaked in the past month will result in very different findings than if the timeframe is narrower. **Additionally, a questionnaire that inquires about bother associated with leakage to define UI will yield varying findings from a questionnaire that merely assesses the presence of the condition.** In a nonmorbid condition such as UI, the impact of the condition on QoL (associated bother) would appear to be of paramount importance. Similarly, studies that rely on the physical demonstration of UI, either on exam or during urodynamics, are likely to report very different findings regarding condition prevalence than those based on questionnaires alone. It is imperative to analyze carefully the incontinence definition used.

Patient populations may also be quite different when assessing epidemiologic aspects of UI. Examining a group of young, nulliparous women, for example, will yield different findings than examining octogenarians living in skilled nursing facilities (O'Halloran et al, 2012). **Clearly, analysis of population gender, comorbidities, access to health care, as well as many other factors will impact the findings greatly.** It is also clear that the geographic location of the study will affect findings—which itself may be a

result of several factors. Although one cannot rule out genetic or environmental factors influencing incontinence rates, the impact of social mores, treatment availability, and education should not be underestimated.

The **type of study** must also be considered. **Case-control studies** are observational studies in which patients are identified who have the condition (incontinence) and are compared retrospectively to patients without the condition. Incidence rates and prevalence rates cannot be generated from this type of study, although one can establish an odds ratio (OR) for associated factors potentially associated with the condition. **Cohort studies** are also observational studies that follow through time a group of patients with a condition. These studies can be either prospective or retrospective and can generate incidence data. **Cross-sectional studies** occur at a single point in time, evaluating for the condition in question, and these studies can generate prevalence data for the condition. Causation, or relative risk, of contributing factors or conditions cannot be established from these types of studies. Although all of the previously mentioned trial designs are susceptible to either various types of bias or confounding factors, **randomized controlled trials (RCTs)** are optimally suited to avoid these pitfalls. RCTs are prospective interventional trials that are ideally designed to not only evaluate outcome of intervention, but also potentially assess relative risk factors for condition prevalence, as well as factors associated with treatment success.

KEY POINTS: FACTORS INFLUENCING THE REPORTED PREVALENCE OF URINARY INCONTINENCE

- Study type
 - Case-control
 - Cohort
 - Cross-sectional
 - Randomized controlled trials
- Demographic factors
 - Age
 - Gender
 - Race
 - Location/nationality
- Presence of comorbidities
- Time period assessed
- Assessment tool used
 - Validated questionnaire
 - Symptom bother assessed
 - Symptom presence assessed
 - Single item on broad health assessment inventory
 - Direct (face-to-face) questioning

Prevalence of Urinary Incontinence in Adult Women

A comprehensive review of epidemiologic aspects of UI summarized data from worldwide studies, focusing on those with favorable (>60%) response rates (Milson et al, 2013). A variety of surveys and survey methods was used in the studies quoted. Overall prevalence rates ranged from as low as 2.8% in a study of younger African women (Ojengbede et al, 2011) to as high as 58.8% in a report from the Netherlands (Sliker-ten Hove et al, 2010). **The majority of studies appear to indicate a prevalence rate for UI between 25% and 40% (Hershorn et al, 2008; Lee et al, 2008; Minassian et al, 2008),** although the rates are age-dependent and studies focusing on younger respondents show lower prevalence rates (Nygaard et al, 2008). As a fraction of incontinence overall, approximately 50% of women reporting leakage will describe stress incontinence, with a slightly lower percentage reporting mixed incontinence, and somewhat fewer describing urgency incontinence. These rates are heavily influenced by the study population, as younger cohorts tend to have more SUI overall, whereas the differences are quite a bit less distinct in older populations (Wehrberger et al, 2012). **Overall,**

prevalence rates of SUI tend to be higher (10% to 25%) than either UUI (3% to 10%) or MUI (5% to 20%).

KEY POINTS: PREVALENCE OF URINARY INCONTINENCE IN WOMEN

- Prevalence rates for UI in women vary considerably depending on the study, but typically range between 20% and 40%.
- Overall, about 50% of reported UI in women is in the form of SUI, with slightly less in the form of MUI, and somewhat less as UUI.
- Younger populations tend to have a greater prevalence of SUI overall, and the differences in prevalence of the different forms of UI tend to be less apparent with older populations.
- Approximately 10% of women experience UI episodes at least weekly.

Because the prevalence rates seem to vary so widely, and study populations often differ considerably, it is inappropriate to generate generalized conclusions from prevalence data. Furthermore, the time interval during which the patients are asked to recount their frequency of leakage tends to differ widely among studies, so even the reported incontinence prevalence rates truly reflect different patient responses. **Ultimately, the majority of the evidence seems to suggest that approximately 10% of women experience at least weekly incontinence episodes**, with certain subpopulations experiencing considerably more. In fact, data suggest that the prevalence of UI, at least in the United States, has risen somewhat during the past decade from 49% in 2001 to 53% in 2008 (Markland et al, 2011). Others have suggested that prevalence rates for pelvic floor disorders, including incontinence, have remained stable recently, although these conditions are still common (Wu et al, 2014) (Fig. 74-2). International estimates appear to be proportionally lower at 21%, although trends suggest that developing nations will be responsible for the majority of new incontinence cases during the coming years (Fig. 74-3) (Irwin et al, 2011).

Incidence and Remission Rates of Urinary Incontinence in Women

Longitudinal studies offer the advantage of the ability to follow groups for potentially extended periods to determine when incontinence is most likely to develop during a woman's lifetime, to determine whether other factors associated with aging might contribute, and to determine whether remission occurs at any time. Studies examining incidence and remission rates of UI may be even more vulnerable to bias and misinterpretation given the high overall prevalence of this condition compared to the relatively low incidence rate. Time between inquiries regarding incontinence, age of the population studied, duration of time that the patient is queried regarding the last time she experienced leakage, and the very nature of the questions asked will often differ considerably among studies. All of these issues must be considered when evaluating reported incidence rates.

When considering middle-aged women (40 to 60), annual UI incidence rates appear to range from 1% to 10%, with higher rates noted when women consider monthly leakage episodes rather than weekly episodes. One extended study following 40-year-old women for 10 years showed that 40% developed new-onset incontinence during this period (Jahanlu and Hunskaar, 2011). As one would expect, SUI is most commonly reported among younger cohorts reporting new symptoms (responsible for 50% of new cases). Interestingly, the incidence of SUI, but not UUI or severe UI, was noted to increase with the menopausal transition from ages 48 to 54 (Mishra et al, 2010). In general, older cohorts have been found to have higher annualized incidence rates—typically between 10% and 20% (Herzog and Fultz, 1990). Among middle-aged or older women, Caucasians, compared to African-Americans, appear more likely to develop UI when followed throughout 5 years (Thom et al, 2010). Those Caucasian women with higher body mass index (BMI) at baseline, and those with weight gain during the survey period, appeared to be at greatest risk. **Annualized resolution rates typically remain less than 5%, although these are noted clearly and consistently in most longitudinal studies.** Higher remission rates have been noted in several studies and may be more typical of studies following younger patients at baseline (Botlero et al, 2011). Interestingly, remission rates may be highest among African-American women (Townsend et al, 2011). The fact that remission

Figure 74-2. Population-based prevalence trends in pelvic floor disorders among nonpregnant women in the United States.

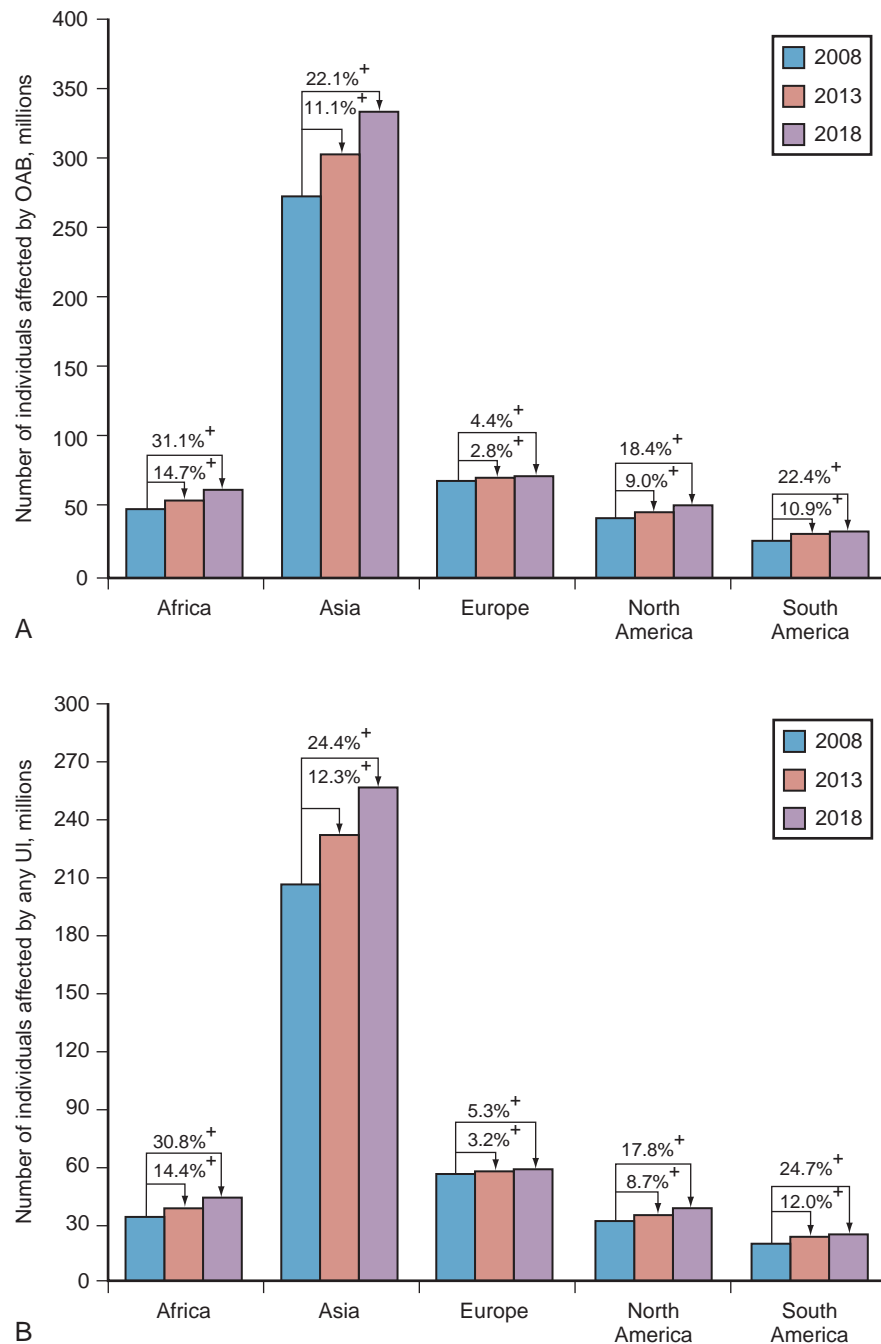

Figure 74-3. Estimated numbers of individuals in major world regions affected by (A) overactive bladder and (B) urinary incontinence.

has been reported emphasizes the existence of transient causes of incontinence, the subjective nature of the condition, and the possibility of recall bias.

KEY POINTS: INCIDENCE AND REMISSION OF URINARY INCONTINENCE

- Annualized incidence rates for UI in women vary between 1% and 10% and are heavily influenced by the population surveyed and the survey tool used.
- A remission rate for UI in women of 1% to 5% has been reported. Remission appears to be higher in younger women.
- Remission rates for men with UI are considerably higher.

RISK FACTORS FOR URINARY INCONTINENCE IN WOMEN

Aging

Although aging alone should not be considered as inevitably linked to UI, it is clear that the vast majority of studies of UI demonstrate a clear association with age that may go beyond the menopausal years—a time when many epidemiologic studies do demonstrate a sharp rise. And although some of the incontinence reported in elderly patients may indeed be attributed to comorbidities, cognitive function, and medication use (as discussed later), age has been recognized as an independent risk factor for UI. In a study of more than 5000 Medicare beneficiaries (all >65) 37% reported UI. There was a clear association with aging noted, even among this

older group (Hawkins et al, 2011). Another survey of nearly 800 community-dwelling women aged more than 65 years showed that 28% of women reported urgency incontinence occasionally or often, whereas 21% reported a similar degree of stress incontinence (Sims et al, 2011). These findings highlight the change in incontinence type that tends to occur with aging, with a shift away from SUI toward MUI and UUI noted in most studies. Interestingly, among older women (>75) UUI appears to be associated with impaired physical mobility, whereas SUI is not (Fritel et al, 2013). Among nonagenarians, UI has been independently linked to frailty and has been established as an independent risk factor for death, suggesting that treatment may be warranted even among the oldest of our patients (Berardelli et al, 2013).

Women living in long-term care facilities (LTCFs) may be at the greatest risk for UI. Several studies have demonstrated the high prevalence of UI in women living in LTCFs (Ouslander et al, 1982; Sgadari et al, 1997; Hunskaar et al, 1998; Saxer et al, 2008). An analysis of nearly 5000 women living in residential care facilities found an incontinence prevalence of more than 40% at admission (De Gagne et al, 2013). Most importantly, severe impairment in the activities of daily living had the strongest association with the presence of UI (OR 21.59). Poor nutritional status, impaired mobility, and increased dementia symptoms all have been correlated with the severity of UI. Importantly, intervening with a group-based behavioral exercise program has been shown to decrease incontinence in women in LTCFs (Tak et al, 2012).

Pregnancy and Postpartum

The prevalence of UI, and in particular SUI, increases during pregnancy and in general increases with gestational age. Overall, the prevalence of SUI during pregnancy is approximately 40%, with more than 50% of affected women reporting a significant impact on QoL (Dolan et al, 2004). By 3 months postpartum, the prevalence of UI drops to approximately 30% and appears to be relatively less severe and imposes much less impact on QoL for most women (Thom et al, 2010). Still, compared to age-matched nulliparous women, primiparous women appear to have a threefold increased likelihood of UI during pregnancy that remains 2.5 times higher 1 year after delivery (Hansen et al, 2012). Interestingly, the magnitude of weight gain during pregnancy does not appear to influence greatly the degree of UI during pregnancy or postpartum, but weight loss postpartum may hasten recovery of continence (Wesnes et al, 2010). In that regard, several studies have demonstrated the protective effect of a properly performed pelvic floor muscle training (PFMT) program in reducing the risk both of UI during pregnancy (Boyle et al, 2008; Stafne et al, 2012) and UI when PFMT is performed immediately postpartum (Ahlund et al, 2013). Regardless of the impact of PFMT postpartum, or the eventual improvement/resolution of UI seen in most women after delivery, the development of UI during pregnancy does reflect a greater likelihood of developing symptomatic UI later in life.

Aspects of Delivery

Whereas pregnancy itself confers an increased risk of UI, mode, duration, and nature of the delivery also appear to influence the risk of UI later in life. Cesarean delivery appears to confer an advantage over normal spontaneous vaginal delivery with regard to the development of UI and SUI (Findik et al, 2012). Five years after delivery, primiparous women who had undergone cesarean section were significantly less likely to report UI overall, although these women may be more bothered by UUI when it occurs than their counterparts (Liang et al, 2013). Similarly a study of women followed for 12 years after delivery noted that, although cesarean section did confer a decreased likelihood of UI, this was only the case if all deliveries were by this method—if other deliveries were vaginal, any protective effect was lost (MacArthur et al, 2011). Other factors such as length of delivery, use of forceps, type of anesthesia,

and use of episiotomy have all been suggested as factors potentially associated with the development of either transient or long-standing UI after delivery, although no conclusive evidence exists to support modifying obstetrical practice based on these findings. In contrast, any history of vaginal birth of a large baby with increased birth weight has been fairly consistently associated with an increased likelihood for developing UI (Connolly et al, 2007; Thom et al, 2011). For example, among women who had at least one child with a birth weight of more than 4 kg, the OR of experiencing weekly UI later in life was 1.47 when compared to those without large babies.

Parity

A single pregnancy and subsequent delivery significantly increase a woman's risk for UI in later life, with an OR of approximately 1.5. Subsequent deliveries increase this risk further (Rortveit et al, 2001; Grodstein et al, 2003; Danforth et al, 2006; Waetjen et al, 2007). Overall, the OR of experiencing any quantity of incontinence later in life among women with 5 or more births, for example, is 1.72 or higher. This risk appears to be accentuated by the timing of the first birth, with those women having their first child closer to the age of 20 seeming to be at greatest risk in most studies, although controversy exists on this topic. As one might suspect, the association between incontinence and parity appears to be strongest for SUI.

Race/Ethnicity

Most cross-sectional studies have indicated that Caucasian women have an increased prevalence of UI and an increased risk for developing incident UI/SUI when compared to African-American women and Asian women (Townsend et al, 2010). Although various explanations exist for this finding, at least one group has noted higher urethral closure pressures in African-American women (DeLancey et al, 2010). This difference in prevalence is less clear when compared to other populations, including Hispanic women. Differences in MUI and UUI based on race are less obvious in comparison and, in fact, are likely inconsequential overall. It appears that Caucasian and African-American women are equally likely to seek care for UI (Berger et al, 2011), although this difference is clearly affected by the degree of leakage (Lewicky-Gaupp et al, 2009). Population-based studies of different cultures, especially those outside the United States, report striking differences in the prevalence of UI in different populations, although these findings are often difficult to interpret based on varying cultural norms and other differences in survey methods.

Hormonal Therapy

Data from several studies suggest that oral estrogen treatment with or without progestogens is associated with the development of UI in middle-aged and older women (Brown et al, 1999). When compared to placebo, the rate of incident incontinence nearly doubled during a 1-year period in a well-conducted large clinical trial of postmenopausal women treated with placebo, estrogen, or estrogen and progestin therapy (Hendrix et al, 2005). By comparison, topical estrogen use is not clearly linked to the development of SUI, and it has proven its efficacy in treating women with vaginal atrophy and recurrent urinary tract infections (UTIs).

Obesity

Both the presence and severity of UI are strongly associated with obesity in women. Although the association appears to be strongest for SUI and MUI, all types of UI have been associated with the development of obesity in women. BMI in excess of 30 has been shown to more than double a woman's risk of UI (Hannestad et al, 2003; Danforth et al, 2006). Whereas symptomatic SUI appears to be more severe and more common in obese women, Valsalva leak point pressure (VLPP) values are higher in women

who are considering surgery for SUI, indicating gradual accommodation of the pelvic floor in women with SUI (Lemack et al, 2007). Incontinence associated with weight gain may be reversible, however, because both surgically induced weight loss and weight loss experienced as a result of a carefully executed weight-loss program have been associated with improvements in UI symptoms that are maintained as long as the weight is kept off (Bump et al, 1992; Richter et al, 2005).

Smoking

Although data remain inconsistent, several compelling studies have demonstrated a link between UI and smoking. A Finnish study of more than 2000 women noted a clear association between symptoms of urinary urgency and frequency and current smoking status. In fact, heavy smoking was associated with more severe urgency symptoms than light smoking (Tahtinen et al, 2011). In a cross-sectional study of more than 80,000 nurses, severe incontinence was associated with current smoking (OR 1.34) (Danforth et al, 2006). Lastly, among women scheduled for SUI surgery, incontinence severity was clearly correlated with current tobacco use. Overall, current smokers had 56% more incontinence episodes than nonsmokers (Richter et al, 2005). Various causes for this link have been suggested, and although some data do question the relationship between smoking and incontinence, there appears to be a growing consensus that some relationship exists.

Diet

Certain foods have been purported to be associated with UI. Overall data are inconsistent, with the association between caffeine (coffee in particular) intake and symptoms of urgency incontinence, mixed incontinence, or OAB generating the most compelling data. Recent data appear to have solidified this link, particularly in men (Davis et al, 2013). There is no consistent link between dietary intake and SUI in most studies. Carbonated beverages and artificial sweeteners have also been primarily associated with urgency symptoms, though confirmatory studies are lacking (Jura et al, 2011).

Medical Conditions

UI appears to be more prevalent among women with certain medical conditions, including diabetes mellitus (DM) and depression. The prevalence of UI among type 2 diabetic women may be as high as two times greater than age-matched nondiabetic women, with emerging evidence suggesting the same finding in women with type 1 DM (Lifford et al, 2005; Phelan et al, 2009a). Among more than 9000 nurses with type 2 DM who were surveyed, 48% reported at least monthly UI, with 29% reporting at least weekly incontinence episodes. Obesity enhanced the risk of UI significantly in this cohort of women (Devore et al, 2012). Similar findings were noted in an interventional trial (weight loss) of obese women with type 2 DM, in whom 27% reported weekly incontinence (Phelan et al, 2009b). The National Health and Nutrition Examination Survey (NHANES) cross-sectional study of 1400 women with type 2 DM additionally identified macroalbuminuria and peripheral neuropathic pain as independent risk factors for UI in patients with type 2 diabetes (Brown et al, 2006). Data from women with type 1 DM is less robust, although a study of more than 500 women demonstrated weekly incontinence in 17% of them, which was a far greater rate in comparison to a nondiabetic cohort from the NHANES analysis (Sarma et al, 2009).

Depression has also been associated with UI in women. It remains unclear whether this association is related to increased bother potentially associated with UI in women with depression, whether incontinence leads to symptoms of depression, or whether there is a common pathophysiologic mechanism for the two. Several studies have demonstrated that the presence of depression leads to an increased likelihood of the later development of UI in women (Thom et al, 1997).

KEY POINTS: RISK FACTORS FOR URINARY INCONTINENCE IN WOMEN

- **Age:** Aging is clearly demonstrated as a potent risk factor for the development of UI in women. Advancing age is clearly linked with a greater likelihood of incontinence and a shift away from SUI to, more commonly, MUI or UUI.
- **LTCFs:** Distinct from aging, maintaining residence in an LTC facility is an independent risk factor for UI. Similarly, severe impairment in activities of daily living has a particularly strong association with UI.
- **Pregnancy and postpartum:** Prevalence of SUI, in particular, increases during pregnancy and increases with gestational age during pregnancy. Prevalence decreases considerably within 3 months postpartum. Properly performed PFMT has been shown to decrease the likelihood of developing SUI.
- **Aspects of delivery:** Cesarean section, when compared to vaginal delivery, appears to confer an advantage with regard to the later development of UI. This advantage may be lost with even one vaginal delivery in addition to the cesarean section. Birth weight of the largest child also appears to be positively correlated with an increased risk of later UI. Other factors such as forceps use and length of delivery have been proposed as risk factors for UI, although overall the association is less clear.
- **Parity:** Whereas a single vaginal delivery increases the risk of UI (and SUI in particular), subsequent deliveries further increase this risk. Age at time of delivery also appears to augment this risk, and those women who are younger when first exposed to pregnancy and delivery appear to be at greatest risk.
- **Race/ethnicity:** An increased prevalence of UI and SUI is noted in Caucasian women when compared to African-American and Asian women. Differences compared to Hispanic populations are less clear. Rates of seeking treatment for UI are similar between African-American and Caucasian women.
- **Hormonal therapy:** Oral estrogen use with or without progestogen is associated with the development of SUI in middle-aged and older women. Topical estrogen has not been clearly associated with this finding, and it can be used for the treatment of vaginal atrophy and, frequently, associated UTIs.
- **Obesity:** The presence and severity of UI is positively correlated with obesity. SUI and MUI are most strongly linked to BMI overall. UI related to weight gain may be reversible in most instances, with either surgical treatment or regimented weight-loss programs providing evidence of substantial improvements in UI.
- **Smoking:** Several compelling studies suggest that symptoms of urinary urgency/frequency, as well as SUI severity (in a surgical cohort), are associated with active smoking. Heavy smokers may be at greatest risk. Data on the impact of smoking cessation are scant.
- **Diet:** The most convincing data with regard to diet and incontinence concern the link between caffeine (coffee in particular) and urgency incontinence/OAB. No clear association exists with SUI. Carbonated beverages and artificial sweeteners have also been associated with UUI, although less clearly so.
- **Medical conditions:** Diabetes and depression are the two most common medical conditions frequently associated with UI. For diabetes, the risk appears to be present in both insulin- and noninsulin-dependent forms, although these are more heavily studied in type 2. Depression in the early years or midlife appears to increase the risk of developing UI later in life.

EPIDEMIOLOGY OF URINARY INCONTINENCE IN MEN

Prevalence, Incidence, Remission Rates

The overall prevalence of UI in men is considerably lower than the rate found in women. In particular, SUI is uncommon in men, with the exception of men who have previously undergone radical pelvic surgery (e.g., radical prostatectomy [RP] or abdominoperineal resection), who have undergone endoscopic transurethral resection of the prostate (TURP) surgery, or who have a neurologic condition that might predispose them to SUI. UUI and MUI are more common in men than SUI, and in many cases these conditions may be attributable to BOO from benign prostatic hyperplasia, other outlet disorders, OAB, or other inflammatory or infectious processes. **Prevalence estimates for UI in men have ranged from 11% to 34% in older men, with up to 11% reporting daily incontinence.** In a telephone survey of more than 14,000 men older than age 40 (mean age 60), 46% reported UI within the previous 4 weeks, although the vast majority reported “other incontinence,” which may have included postvoid dribbling (Buckley et al, 2010; Markland et al, 2010; Coyne et al, 2012). Matched for age, UUI or MUI are more prevalent forms of UI in men than in women, particularly for younger men. As with women, estimates vary considerably dependent on the tool used to assess for UI, the timeframe used, and the population surveyed.

The likelihood of developing UI is age dependent. Several studies have indicated an incidence rate of approximately 1% to 10% annually in men from 60 to 70 years of age followed for 5 to 10 years (Herzog and Fultz, 1990). The remission rate for UI tends to be higher in men than in women. This is largely because of the fact that leakage in men is more typically urgency related, which may have several reversible (infectious/inflammatory) causes. **Depending on the age studied, remission rates as high as 40% have been noted in men with UI (McGrother et al, 2004).**

Risk Factors for Urinary Incontinence in Men

Age appears to be the strongest independent risk factor for UI developing in men—an association that might be even stronger than that noted in women (Diokno et al, 2007). Men appear to be particularly vulnerable to UI with infectious processes such as acute cystitis and prostatitis, the prevalence of which are also clearly associated with aging. Similar to findings in women, altered cognition, diminished mobility, and the presence of other comorbidities are all associated with an increased likelihood of UI. Certain neurologic conditions more commonly found in aging populations (Parkinson disease, cerebrovascular accident [CVA]) are also associated with incontinence in men, most commonly UUI.

RP and other radical pelvic surgeries have been associated with the development of UI in men. The likelihood of UI varies considerably, with overall estimates ranging from 8% to 60% at 1 year following RP (Ficarra et al, 2009). **The absence of preexisting LUTS/previous TURP, technique of surgery (bladder neck sparing and neurovascular bundle sparing), and younger age at the time of surgery have all been shown to be associated with a lower risk of postoperative UI, although conflicting data exist (Gupta et al, 2011).** The postoperative impact of robotic-assisted approaches to RP on UI incidence rates has been modest, with the most recent studies noting incontinence rates comparable to the open approach. When compared to a laparoscopic approach, robot-assisted RP appears to result in earlier return to continence and overall improved continence (95% vs. 83% at 1 year) (Porpligia et al, 2013). In comparison, TURP, whether performed with electrosurgical cauterization or using the potassium titanyl phosphate (KTP) laser approach, is associated with a low (1%) likelihood of developing UI postoperatively.

KEY POINTS: EPIDEMIOLOGIC ASPECTS OF URINARY INCONTINENCE IN MEN

- UI is considerably less prevalent in men than in women.
- UUI is the most common form of UI in men, followed by MUI and then SUI.
- SUI in men is associated with previous radical pelvic surgery (in particular RP) and certain neurologic diseases.
- SUI prevalence rates following RP range from 8% to 60%.
- Robotic prostatectomy leads to an earlier return to continence and lower UI overall compared to the laparoscopic approach. There is no clear consensus that the robotic approach has led to a lower incidence of postoperative UI compared to an open approach.
- Remission rates for UI are considerably higher in men than in women. Remission rates as high as 40% have been reported.
- Age is even more closely associated with the development of UI in men than in women.

DEFINITIONS AND CLASSIFICATION OF PELVIC ORGAN PROLAPSE

POP refers to “downward descent of the female pelvic organs, including the bladder, uterus, or posthysterectomy vaginal cuff, and the small or large bowel, resulting in protrusion of the vagina, uterus, or both” (Jelovsek et al, 2007). **Anterior compartment prolapse** refers to a weakness of the anterior vaginal wall often associated with the descent of the bladder (cystocele). **Posterior compartment prolapse** is a weakness of the posterior vaginal segment often associated with bulging of the rectum into the vagina (rectocele) but can include the small intestine (enterocele). Rectoceles are usually associated with perineal descent, or weakening of the perineal body. **Apical prolapse** entails descent of the uterus, or in the posthysterectomy patient, the vaginal cuff. **Enterocoele** is a true hernia of the intestines into the vaginal wall. Enterocoeles may be an asymptomatic consequence of apical vaginal prolapse, but can also be associated with significant defecatory dysfunction when they are located between the posterior vagina and rectum (Takahashi et al, 2006), even when the apex is well supported. **Uterine procidentia** refers to total vaginal eversion with stage IV uterine prolapse.

Symptoms of Pelvic Organ Prolapse

A multitude of symptoms can be attributed to POP. However, **sensation of a vaginal bulge remains the only symptom that is strongly associated with prolapse at or below the hymenal ring (Tan et al, 2005).** Other symptoms, including UI and fecal incontinence, voiding and defecatory difficulty, and sexual dysfunction, frequently coexist with POP, but they correlate weakly with the severity or site of POP (Ellerkmann et al, 2001). If a woman presents with pelvic pain or pressure primarily, it is imperative to consider other sources of her symptoms, such as endometriosis, adnexal masses, or other forms of pelvic pathology. Placement of a pessary can help to determine whether pain or other vague symptoms of pressure are a result of prolapse. If the pessary relieves symptoms, then the POP is the likely cause of symptoms. Rectocele symptoms are easily confused with defecatory dysfunction resulting from constipation. **In general, defecatory symptoms alone in the absence of specific sensation of a vaginal bulge would only rarely be an adequate reason to intervene surgically for posterior compartment prolapse.** Hence a specific inquiry should be made about whether defecatory symptoms persist even in the absence of constipation, and whether the patient feels as though bowel movements get caught “in a pocket” (the rectocele defect) during defecation. Women with symptomatic rectoceles may, on their own accord, place fingers in the vagina or

Figure 74-4. Pelvic Organ Prolapse Quantification system and specific points measured. gh, genital hiatus; pb, perineal body; tvl, total vaginal length.

perineum to help evacuate a bowel movement, which is a behavior known as “splinting.”

Physical Examination of Pelvic Organ Prolapse

The Baden-Walker halfway scoring system for the evaluation of POP uses the hymen as the reference point. Grade 0 is considered normal, grade 1 descent halfway to the hymen, grade 2 descent to the hymen, grade 3 descent halfway past the hymen, and grade 4 maximum possible descent for each site. Although widely used, interobserver agreement is variable with the Baden-Walker system, and there is a lack of information about the exact location of specific sector defects (Persu et al, 2011).

In 1993 an international multidisciplinary group composed of members of the ICS, the American Urogynecologic Society, and the Society of Gynecologic Surgeons developed a standardization document that was then adopted by these specialty societies, was published in 1996 (Bump et al, 1996), and was updated in 2002 (Abrams et al, 2002). The Pelvic Organ Prolapse Quantification (POPQ) system provides a precise, objective description of a woman's pelvic support that defines POP relative to a fixed reference point, the hymen. Negative numbers refer to points inside the introitus, and positive numbers reflect prolapse outside the introitus (Fig. 74-4). Point Aa refers to a point on the anterior vaginal wall that is 3 cm proximal to the urethral meatus. It is meant to estimate the position of the bladder neck/proximal urethra junction in most women. Aa ranges from -3 cm to $+3$ cm (-3 cm in the absence of prolapse or urethral hypermobility). Urethral hypermobility can be measured using the POPQ system, eliminating the need to perform a Q-tip test. Point Ba refers to the most dependent portion of anterior vaginal wall prolapse (from the vaginal apex to point Aa). Two points reflect the vaginal apex, which are point C (either the cervix or the vaginal cuff/hysterectomy scar) and point D (the point denoting the posterior fornix in a woman who still has a cervix). Point D, when compared to point C, will differentiate cervical elongation from uterine prolapse. The posterior vaginal wall points include point Bp (the most distal prolapse of the posterior vaginal wall) and Ap (the point located 3 cm from the hymen), which is meant to parallel the Aa point. The genital hiatus (gh) is measured from the middle of the urethral meatus to the posterior midline hymen. The perineal body (pb) is measured from the posterior margin of the genital hiatus to the midanal opening. The total vaginal length (tvl) is the greatest depth of the vagina in centimeters when the vagina is fully reduced. Points Aa, Ba, Ap, Bp, C, and D are measured with the patient straining, so as to accentuate maximal prolapse during the examination. See the video on the Expert Consult website for instructions on how to conduct a POPQ exam.

anterior wall Aa	anterior wall Ba	cervix or cuff C
genital hiatus gh	perineal body pb	total vaginal length tvl
posterior wall Ap	posterior wall Bp	posterior fornix D

Figure 74-5. The 9-point Pelvic Organ Prolapse Quantification scoring system placed on a 3×3 grid. gh, genital hiatus; pb, perineal body; tvl, total vaginal length.

Figure 74-6. A, Pelvic Organ Prolapse Quantification (POPQ) description of patient with total vault eversion posthysterectomy. B, Woman with no prolapse (normal POPQ measurements). gh, genital hiatus; pb, perineal body; tvl, total vaginal length.

The 9-point scoring system is placed on a three-by-three grid (Fig. 74-5) (Bump et al, 1996). Measurements may also be recorded as a line of numbers for points Aa, Ba, C, D, Bp, Ap, tvl, gh, and pb, respectively. Stages are assigned to the most severe portion of the prolapse when the full extent of the prolapse has been demonstrated (usually with straining). Stage 0 is without prolapse (points Aa, Ap, Bp are all at -3 , and point C or D is between $-tvl$ and $-[tvl - 2]$ cm). In stage 1 POP, the distal portion of the prolapse is more than 1 cm above the level of the hymen. In stage 2, the distalmost aspect of the POP is found within 1 cm on either side of the hymen. In stage 3, the distalmost portion of the prolapse is more than 1 cm below the hymen but not totally everted (no further than 2 cm less than tvl, or $> +1$ cm but $< +[tvl - 2]$ cm). Stage 4 is complete vaginal eversion ($\geq +[tvl - 2]$ cm). Figure 74-6 demonstrates POPQ measurements in a woman with normal anatomy and a woman with stage 4 posthysterectomy vaginal vault eversion.

For most clinicians, radiologic studies play a relatively small role in the evaluation of POP; the physical examination with the POPQ system quantifies most defects such that further information is often not needed for treatment planning. A static cystogram followed by a voiding cystourethrogram, performed in the standing position is used by some clinicians to establish urethral position, and may assist in assessing the impact of prior procedures on the urethral axis. Resting and straining magnetic resonance imaging (MRI) has become integrated into the diagnostic workup of POP in some centers and can specifically aid in diagnosing the presence of an enterocele (Fig. 74-7A and B). Defecography is also valuable in determining the presence of enterocele in women with defecatory dysfunction, and this procedure likely has better sensitivity than MRI because women are in the upright position during defecography, which may better demonstrate pelvic prolapse. MRI

Figure 74-7. A, Magnetic resonance image (MRI) of female pelvis with isolated cystocele defect. B, MRI of female pelvis with isolated enterocele defect. (From De Almeida FG, Rodriguez LV, Raz S. Magnetic resonance imaging in the diagnosis of pelvic floor disorders. *Int Braz J Urol* 2002;28:553–9.)

defecography is a new tool that also has been used in certain centers to characterize prolapse better, particularly in the differentiation of enterocele. The cost effectiveness and overall benefit of radiologic studies in the evaluation of women with POP have not been carefully scrutinized and therefore still should be used at the discretion of the treating physician. For the majority of patients, a careful POPQ physical examination and, if necessary, reassessment at the time of surgery remain the cornerstones of POP assessment.

EPIDEMIOLOGY OF PELVIC ORGAN PROLAPSE

Prevalence and Incidence

Identifying POP based on self-reported symptoms is difficult because of the lack of specificity and sensitivity of most symptoms

attributed to POP (Ellerkmann et al, 2001). The greatest challenge in studying the prevalence of POP rests in the fact that POP develops well before it becomes symptomatic, and POP above the hymenal ring is usually asymptomatic. In fact, in a multicenter observational study of 1004 women aged 18 to 83 years seen for routine annual gynecological examinations, the prevalence of stages 0 to 3 POP was 24%, 38%, 35%, and 2%, respectively (Swift et al, 2005). Therefore asymptomatic stages 1 to 2 POP are considered normal in adult women. Similarly, in the Women's Health Initiative, which measured prolapse in postmenopausal women with physical examination, the overall presence of prolapse was 41% for women with a uterus and 38% of women posthysterectomy (Hendrix et al, 2002).

Additionally, individual women experience symptoms of prolapse differently in that some women may be symptomatic with stage 2 POP whereas other women will have no symptoms. A study suggests that ethnic background may influence symptoms associated with POP (Dunivan et al, 2014b). In this study, the authors noted that degree of bother from stage 2 POP was higher in Hispanic and Native American women compared with Caucasians. Because treatment is generally indicated for women with symptoms, the distinction between symptomatic and asymptomatic POP is relevant.

The prevalence of POP based on a sensation of a mass bulging into the vagina or observed on pelvic examination is between 4% and 12.2% (Hunskar et al, 2005; Sliker-ten Hove et al, 2009). In contrast, questionnaire-based estimates likely under-report the true prevalence of POP based on physical examination. Few studies report on the incidence of POP. In a subgroup analysis of women enrolled in the Women's Health Initiative Estrogen Plus Progestin Trial, Handa and colleagues (2004) found that the annual incidence of new cystoceles was 9.3 cases per 100 women-years, rectocele 5.7 cases, and uterine prolapse 1.5 based on physical examination. Most epidemiologic analyses suggest that prolapse occurs most frequently in the anterior compartment, followed by the posterior compartment, and least commonly in the apex. Although this finding is well supported in the epidemiologic literature, it is clear that both high-grade anterior and posterior prolapse are frequently associated with coexisting apical descent.

Risk Factors

Well-established risk factors for POP include parity, age, and obesity. Childbirth is associated with an increased risk of POP later in life, and current evidence suggests that parity also contributes. In the Oxford Family Planning Study, which is a prospective cohort study of more than 17,000 women, parity was the strongest risk factor for the development of POP with an adjusted relative risk of 10.85 (95% confidence interval [CI] 4.65 to 33.81) (Mant et al, 1997). Although the risk increased with each delivery, the rate of increase slowed after the first two deliveries. Nonetheless, a case-control study by Moalli and colleagues (2003) showed that women who had a vaginal delivery had 2.9 times the risk of undergoing surgery for POP or UI (95% CI 0.9 to 10.0) and women who had forceps delivery had 5.4 times the risk (vs. cesarean delivery, 95% CI 1.6 to 18.4). Although cesarean delivery is associated with a decreased risk of POP compared to vaginal delivery, the degree to which cesarean delivery prevents the development of POP is unknown, especially after multiple cesarean deliveries. As with UI, both the incidence and prevalence of POP increase with age (Hunskar et al, 2005). Surgery for POP and UI also increase with age, reaching a peak in the seventh decade (Olsen et al, 1997). Obesity is not only a risk factor for the development of POP, but it is associated with early recurrence of anterior vaginal wall prolapse after anterior colporrhaphy (OR 2.5, 95% CI 1.2 to 5.3) (Kawasaki et al, 2013).

Several other important, yet less well-established, POP risk factors exist. These include race/ethnicity and increasing weight of the vaginally delivered fetus. Two studies that examined POP by race showed that black women had the lowest prevalence of POP and Hispanic women the highest prevalence after controlling for other possible confounding factors. Based on symptoms, Rortveit

and colleagues (2001) found adjusted ORs of 9.4 (95% CI 0.2 to 0.8) for black and 1.3 (95% CI 0.8 to 2.2) for Hispanic women, with white women as the reference group. Based on physical examination, Hendrix and colleagues (2002) similarly found adjusted ORs of 0.6 (95% CI 0.5 to 0.8) for black women and 1.2 (95% CI 1.0 to 1.5) for Hispanic women. An association between **maximum birth weight** and the development of POP has also been found (Samuelsson et al, 1999). **Hysterectomy and other pelvic surgery** may increase the risk of POP (Hunnskaar et al, 2005). In fact, hysterectomy performed for POP is a strong predictor of the need for repeat pelvic floor surgery, although this in part might be a result of failure to perform concomitant vaginal vault suspension at the time of hysterectomy. Based on twin studies, POP includes **familial transmission** patterns mediated by genetic factors (Hunnskaar et al, 2005). Other identified risk factors for the development of POP include **smoking, chronic constipation, and menopause/hormonal effects**.

KEY POINTS: EPIDEMIOLOGY OF PELVIC ORGAN PROLAPSE

- The prevalence of symptomatic prolapse ranges from 4% to 12%, although asymptomatic prolapse is present in the majority of adult women.
- Both the incidence and prevalence of POP increase with age, as do rates of surgery for POP.
- Parity is associated with an increased risk for POP later in life. Current evidence also suggests that an increasing number of childbirths increases the risk of POP, although the rate of increase slows after the first two deliveries.
- Obesity is not only a risk factor for the development of POP, but it is associated with early recurrence of anterior vaginal wall prolapse after anterior colporrhaphy.
- Hysterectomy and other pelvic surgery may increase the risk for POP, and hysterectomy for POP is a strong predictor of secondary pelvic floor surgery.
- Cesarean delivery is associated with a decreased risk for subsequent pelvic floor morbidity in comparison to giving vaginal birth, but whether cesarean delivery prevents the development of POP remains uncertain.
- POP is more common in Caucasian and Hispanic women when compared with African-American women.

RELATIONSHIP BETWEEN URINARY INCONTINENCE AND PELVIC ORGAN PROLAPSE

Many of the etiologic risk factors that contribute to SUI are similar to those described for POP. In fact, more than 40% of women with SUI will have a significant anterior vaginal prolapse (Cardozo and Stanton, 1980). In addition, **high-stage cystocele might mask "occult" SUI by creating urethral obstruction**. Often, as anterior prolapse stage progresses in severity, previously incontinent women will notice an improvement in their SUI symptoms. Our understanding about why some women develop symptoms of SUI without POP and others develop POP without SUI is limited (Bidmead et al, 2001). POP can **exacerbate storage symptoms**, and the two conditions are frequently associated. Enhorning found that women with mild cystoceles experienced a 20% incidence of detrusor overactivity (Enhorning, 1961). This increased to 52% among women with moderate to severe cystoceles. **Improvement of OAB symptoms can be expected after POP surgery in a significant proportion of patients** (de Boer and Vierhout, 2011). In fact, Fletcher and coworkers (2010) found that anterior compartment repair resulted in a reduction of frequency (by 33%), UUI (49%), and difficulty voiding (74%) at a median of 21 months' follow-up. Persistent UUI after repair was related to a higher preoperative P(det)Q(max) (OR 1.056, 95% CI 1.003 to 1.11, $P = .04$).

Failure to recognize POP at the time of UI treatment might greatly increase the need for subsequent surgery for POP (Anger et al, 2007). Data from a 5% national random sample of 1999 to 2001 Medicare claims for patients undergoing UI surgery showed that urologists performed concomitant prolapse repairs at the time of sling in 29.1% of cases, whereas gynecologists performed prolapse repairs in 55.7% ($P < .0001$). In the 12 months following sling surgery, patients who underwent surgery by a urologist were more likely to undergo a repeat surgery for prolapse repair (26.0% vs. 12.2%, $P < .0001$). These findings emphasize the importance of identifying and managing symptomatic prolapse when evaluating patients with UI.

In addition, **procedures for UI can exacerbate certain types of POP**. The classic Burch colposuspension, which corrects SUI and anterior prolapse by suspending the anterior vagina at the level of the bladder neck to Cooper ligament, has been shown to contribute to the later development of uterine prolapse and/or enterocele by changing the vaginal axis and bringing it to a more anterior position (Langer et al, 1988).

Women with high-stage anterior vaginal wall prolapse are also at risk of developing "de novo" SUI should they undergo surgery for POP. In fact, a multicenter trial by the Pelvic Floor Disorders Network randomized women without symptoms of SUI to receive a concomitant midurethral sling (vs. sham) at the time of vaginally approached prolapse surgery (Wei et al, 2012). At 1 year after surgery, 27.3% of women in the sling group experienced incontinence vs. 43% in the sham group ($P = .002$). However, complications were increased among those who underwent a sling, including bladder perforation in 6.7% (vs. 0%), UTIs (31.0% vs. 18.3%), major bleeding complications (3.1% vs. 0%), and incomplete bladder emptying 6 weeks after surgery (3.7% vs. 0%, $P \leq .05$ for all comparisons). Other risks of sling placement, such as de novo urgency, although not mentioned, should also be carefully considered in a patient without incontinence symptoms. **This study emphasizes the relationship between anterior vaginal prolapse and SUI, and also the need to consider prophylactic sling placement at the time of POP surgery for women who do not report SUI, while carefully weighing the potential for additional risks associated with this approach.**

KEY POINTS: CONDITIONS ASSOCIATED WITH PELVIC ORGAN PROLAPSE

- More than 40% of women with SUI will have a significant cystocele.
- Occult SUI is urethral sphincteric incompetence masked by the presence of high-stage anterior POP. Failure to address occult SUI at the time of surgery for POP may lead to more severely symptomatic SUI postoperatively.
- POP may be associated with defecatory dysfunction and fecal incontinence. Disorders of defecation, including fecal incontinence and urgency, should be carefully evaluated before considering POP surgery.
- Sexual dysfunction is often associated with both POP and UI. Treatment of these conditions may ameliorate symptoms of sexual dysfunction. Still, dyspareunia has been associated with some types of POP repair, and, as such, changes in sexual function are an important aspect of preoperative counseling.

CONSEQUENCES OF URINARY INCONTINENCE AND PROLAPSE

Societal Costs of Urinary Incontinence

The cost of diagnosing and treating UI is significant. Estimates of cost are difficult to make, as they include many variables not easily quantified in health care cost analyses, including many

out-of-pocket expenses that place the financial burden squarely on individuals rather than on government or third-party payers. Therefore, in addition to the costs of diagnostic studies, office visits, medications, surgeries and other interventions, and treatment of related UTIs or care for skin breakdown, one must take into account personal expenses related to absorbent products, increased laundering related to leakage, missed work, and other personal costs. A review of the financial burden associated with the management of female SUI alone reported annual costs in excess of \$12 billion in the United States, with more than 70% considered out-of-pocket expenses (Chong et al, 2011). A report from the Urinary Incontinence Treatment Network noted that women with severe incontinence had \$900 of out-of-pocket expenses annually for incontinence routine care (absorbent products, laundry, and so forth) (Subak et al, 2006). With regard to OAB, if one uses a prevalence estimate of 42 million Americans affected, a societal cost of \$25 billion annually has been estimated, based on outpatient visits, medical treatments, work time lost, as well as other related expenses (Onukwugha et al, 2009).

Social Impact of Urinary Incontinence

The impact of UI and OAB on patients' lives has been studied in detail. Nearly every aspect of a patient's life is affected by the development of UI (Coyne et al, 2012). Relationships are clearly affected, and sexual activity may be severely limited by the threat of UI. It is clear that young and old, patient and partner, are all affected by the impact of UI on sexual activity, and that surgery to improve incontinence has a positive effect on sexual function (Brubaker et al, 2009; Nilsson et al, 2009). Patients often restrict travel, even for short distances, because of the fear of major leakage episodes when not in close proximity to a toilet. UI affects what patients eat and drink (avoiding foods they may enjoy), what they wear (wearing dark clothing to guard against obviating leakage), and with whom they associate (avoiding people they do not know). They may have decreased work productivity because they need to urinate often (or desire to urinate to try to avoid leakage episodes). Because sleep disturbances are more common in some forms of UI, daytime alertness and productivity might be affected as well.

UI appears to affect the QoL of patients at all ages. Young nulligravid women with incontinence report greatly diminished overall well-being compared to age-matched women without UI (O'Halloran et al, 2012). Elderly patients are affected as well, with the severity of UI rather than the type of UI primarily responsible for the impact on QoL (Aguilar-Navarro et al, 2012; Barentsen et al, 2012). The impact of UI is seen in nearly all QoL domains, and the severity of impact may be greater than that seen with other common conditions associated with aging, including arthritis and diabetes (Hawkins et al, 2011).

KEY POINTS: CONSEQUENCES OF URINARY INCONTINENCE

- Societal costs of UI are difficult to estimate because of the considerable burden on patients not covered by conventional third-party insurers. Tens of billions of dollars are estimated at a minimum for the societal costs associated with UI.
- Interpersonal relationships are affected in a variety of ways. Sexual activity may be curtailed because of concerns regarding incontinence. This finding is true regardless of age.
- Virtually all QoL domains are impacted by UI. Travel, leisure, and recreational activities are often restricted. Diet is often adjusted (particularly in patients with OAB symptoms).
- Sleep disturbances are often associated with certain types of UI.
- Loss of work productivity has been associated with UI.

Societal and Personal Costs and Consequences of Pelvic Organ Prolapse

Olsen and coworkers (1997) reported an 11% lifetime risk of surgery for POP or UI in a Kaiser Permanente population of women in the Pacific Northwest. Reoperation for failed procedures was 29%. Smith and coworkers (2010) reported a 19% lifetime risk of undergoing prolapse surgery in Western Australia. POP is the most common noncancer indication for hysterectomy among menopausal women in the United States (Wilcox et al, 1994; Swift et al, 2005). In the United States, more than 300,000 surgical procedures for POP are performed annually, with 25% undergoing reoperations (Maher et al, 2013). The annual incidence of POP surgery ranges from 1.5 to 4.9 cases per 1000 woman-years (Hunnskaar et al, 2005). The incidence rises with age, approaching 3.3 cases per 1000 woman-years among women aged 50 and older (Boyles et al, 2003). U.S. costs for POP and UI are more than \$1 billion per year (Olsen, 1997). In 1997, the direct costs of POP surgery were \$1.012 billion, including \$494 million (49%) for vaginal hysterectomy, \$279 million (28%) for cystocele and rectocele repair, and \$135 million (13%) for abdominal hysterectomy (Subak et al, 2001). Using the 2007 Nationwide Inpatient Sample and the 2006 National Survey of Ambulatory Surgery, Wu and colleagues (2011) calculated the rates for inpatient and outpatient SUI and POP surgery and estimated that the number of those who will have surgery for prolapse will increase from 166,000 in 2010 to 245,970 in 2050. Even if the overall surgery rates for pelvic floor disorders remain unchanged, it has been predicted that the number of surgeries for UI and POP will increase substantially during the next 40 years.

POP has a significant negative impact on QoL. Similar to UI, POP is not discussed freely in public, and therefore women often experience shame about the condition and do not discuss it with others (Dunivan et al, 2014a). POP is associated with both decreased body image (Jelovsek and Barber, 2006) and sexual dysfunction. In fact, in a population of women with UI, women with both POP and UI were more likely to report decreased libido, decreased sexual excitement, and difficulty achieving orgasm when compared to women with UI alone (Ozel et al, 2006). Although POP is generally considered a QoL condition with few medical sequelae, untreated prolapse can become advanced to a point when a woman can develop urinary retention from urethral compression and, rarely, renal failure from ureteral compression (Young et al, 1984).

PHYSIOLOGY OF URINARY CONTINENCE

Overview of Normal Continence Mechanisms

Urinary continence is maintained via an interplay of complex neural, structural, and ultrastructural mechanisms involving the lower urinary tract and surrounding structures. Failure of any one of these contributing factors can lead to UI. Some common pathologies may affect more than one of these mechanisms, leading to fairly severe UI. For example, the effects of external-beam radiation may be realized years, even decades, following initial treatment. In addition to profound effects on nerve structure and function (which can affect bladder sensation and induce overactivity), radiation can affect bladder storage pressures by increasing bladder wall rigidity through changes in smooth muscle elasticity and extracellular matrix composition.

Neural Control of the Lower Urinary Tract

Bladder storage at its very essence is a neurologically mediated event. Parasympathetic transmission (via the pelvic nerve) is suppressed and sympathetic transmission (via the hypogastric nerve) is active, and both are imperative to the creation of a low-pressure reservoir that is maintained during the entirety of the filling phase. Spinal reflex mechanisms allow afferent signaling from the bladder (via A delta myelinated nerves) to promote sympathetic-mediated closure of the bladder neck, a closure mechanism that is decidedly stronger in men than in women. The pontine micturition

center in the brainstem integrates afferent input and ultimately is responsible for parasympathetic-mediated bladder contraction (Drake et al, 2010). However, before a coordinated contraction, tonic inhibition of coordinated parasympathetic activity by suprapontine centers prevents bladder contraction. Additionally, ongoing pudendal nerve activation (via Onuf nucleus in the sacral cord) of the external sphincter mechanism results in the continuous resistance required to maintain continence during bladder filling.

The Bladder: An Organ Capable of Significant Expansion at Low Pressures

The position of the bladder itself also provides a unique ability to allow for significant expansion, while placing the vulnerable sphincteric unit in a more protected environment where external forces are less likely potentially to influence the ability of the outlet to maintain continence (particularly in men). The dome of the bladder can expand well into the peritoneal cavity with relatively no extravescical force opposing this expansion. In contrast, the bladder base and neck sit in a stable retropubic location. In men, this position is essentially fixed and immobile, and unless neurologic/traumatic/operative events occur, only a direct impact on the sphincteric unit itself will result in leakage. In women, where pelvic floor laxity can impact bladder neck position and function, incontinence may result, at least in part, from changes in the position of the bladder outlet.

The structure of the bladder wall and characteristics of smooth muscle cells allow for passive filling without increases in pressure that would create undue forces on the bladder outlet. Relatively poor coupling between detrusor smooth muscle cells appears to contribute to the ability of the bladder to avoid the propagation of unplanned spontaneous smooth muscle contractions into a coordinated bladder contraction during filling. Although individual smooth muscle cells may be triggered to contract by stretching during bladder fill, in most situations a sustained bladder contraction requires coordinated parasympathetic stimulation. The multiple-layered mucosal lining of the bladder itself further enhances the ability of the bladder to store urine, as the urothelial cell layers (“umbrella cells”) can flatten considerably with filling. Further, the extracellular matrix composition of the bladder wall, and in particular the type of collagen (type I favored in normally compliant bladders), as well as the collagen-to-elastic ratio, are critical to the maintenance of a low-pressure state in the bladder during normal filling.

KEY POINTS: FACTORS CONTRIBUTING TO LOW-PRESSURE RESERVOIR DURING BLADDER FILLING

- **Neural:** Parasympathetic suppression, sympathetic activation promotes detrusor relaxation.
- **Anatomic (gross):** Intraperitoneal position of bladder dome permits unimpeded expansion.
- **Anatomic (micro):**
 - Multilayered mucosal layer of bladder promotes expansion with filling, collapse with emptying.
 - Poor coupling between detrusor smooth muscle cells dissipates aberrant contractions.
 - Extracellular matrix composition promotes minimal change in bladder pressure by enhancing bladder elasticity. Collagen type I is major collagen subtype.

Bladder Outlet/Sphincteric Mechanisms

Maintenance of a low-pressure reservoir would be of no value in assuring continence if not for the presence of sufficient outlet resistance (higher than storage pressures). A competent bladder outlet results from specific urethral mucosa attributes, which are the so-called internal sphincter (intrinsic properties of the

Figure 74-8. Male urethral sphincter complex. 1, Bladder musculature. 2, Proximal part of internal sphincter. 3, Distal part of internal sphincter. 4, Rhabdosphincter. 5, Prostatic part of rhabdosphincter. 6, Perineal membrane. 7, Prostate.

bladder neck/proximal urethra) and the distal (rhabdo) sphincter. Urethral mucosal longitudinal folds allow for both distensibility (for opening during voiding) and contribute to the creation of a mucosal “seal” that enhances urethral closure during bladder filling. The well-vascularized spongy submucosal layer contributes to the distensibility of the urethral lumen. Additionally there are important structural and functional differences characterizing the sphincteric units in men and women that help to explain further how incontinence can be maintained in each of the sexes.

Male Sphincteric Mechanisms

The internal sphincter is a contributory continence mechanism extending from the bladder neck to the distal verumontanum. In the absence of disease or injury, urine commonly does not descend beyond the bladder neck to the level of the external sphincter. Dryness created by the forces at the bladder neck is, in part, a result of α -adrenergic activation of smooth muscle at the bladder neck (sometimes called the lissosphincter) and within the prostatic urethra. This smooth muscle extends distally and then toward the rhabdosphincter where the greatest intraurethral forces are generated (Koraitim, 2008) (Fig. 74-8). Sympathetic innervation of this zone, when combined with β -adrenergic-stimulated relaxation of the bladder body, promotes dryness. Other aspects of the internal sphincter continence unit include the prostate itself, which further enhances outlet resistance. Because of these factors, loss of external sphincter function, such as with traumatic pelvic injury, may not result in incontinence in men with an intact bladder neck. This is in contradistinction to the bladder neck in women, which is relatively weak, making women more vulnerable to incontinence with any deficiency of external sphincter function.

The external sphincter is largely composed of skeletal muscle and as such has the ability to create intense compressive forces. Indeed, pressures at the rhabdosphincter are in excess of 40 cm water continuously during bladder filling, and these pressures can rise considerably further with voluntary contraction. Pudendal nerve injury or denervation can result in the loss of external sphincter strength and subsequent UI (Sajadi et al, 2012; Gill et al, 2013). The strength of the external sphincter is highlighted in the presence of the failure of and/or the injury to the bladder neck (i.e., during TURP), in which case the presence of an intact rhabdosphincter nearly always results in the maintenance of continence. The rhabdosphincter is a concentric muscle composed largely of type I (slow-twitch) skeletal muscle, although smooth muscle fibers are noted to intermingle with the more prominent skeletal muscle bundles. The presence of slow-twitch fibers is what is largely responsible for the tonic ability of the sphincter to maintain urethral closure essentially in a continuous fashion during bladder filling. Fast-twitch fibers found in the surrounding levator musculature contribute then to the ability transiently to enhance voluntary closure during times of increased stress on the sphincteric

unit. Further anatomic support of the rhabdosphincter is derived from the pubourethral ligaments, which serve to anchor the sphincteric unit solidly in an anterior position. Ventral support of the sphincter comes from the condensation of musculofascial elements that ultimately fuse at the perineal body. This unique arrangement of the male sphincteric unit stabilizes and protects the sphincter from the impact of external forces.

KEY POINTS: CONTINENCE MECHANISMS OF THE BLADDER OUTLET AND URETHRA IN MEN

- Internal sphincter:
 - α -adrenergic activation of bladder neck and prostatic smooth muscle
 - Prostatic restrictive forces on urethra
- External sphincter:
 - Rhabdosphincter (largely slow-twitch type I skeletal muscle) provides tonic compression
 - Levator muscular elements (fast-twitch) assist during times of increased stress on external sphincter
 - Anterior fixation by pubourethral ligaments
 - Posterior support of musculofascial plate fusing at perineal body

Female Sphincteric Mechanisms

Unlike the powerful continence zone created at the level of the bladder neck in men, continence in women is largely a result of forces created along the proximal urethra and/or midurethra, in addition to somewhat less forceful distal urethral muscular contributions. **Indeed it is fairly common for the bladder neck to be incompetent in women, although continence remains intact (Chapple et al, 1989; Versi et al, 1990).** As in men, longitudinal smooth muscle courses toward the external sphincter, although the bulk of the muscle responsible for sphincteric control in women is circular striated muscle located in the proximal urethra and/or midurethra. Muscular forces (primarily striated muscle) create a nearly complete circumferential compression of the midurethra (DeLancey, 1988) under the influence of tonic pudendal innervation. Experimental studies in rats have demonstrated both transverse and longitudinal orientation of striated muscle inserting directly into the connective tissue of the urethral wall (Mondet et al, 2003) (indicating both circular and longitudinal muscle orientation). Pudendal denervation and resultant sphincteric weakness, potentially occurring as a result of prolonged labor, is one mechanism by which incontinence may result from the effects of labor and delivery.

More distally, striated muscular fibers are not oriented circularly but are located ventrally. These muscular fibers contribute to the compressor urethra (which originates in the perineal membrane) and urethrovaginal sphincter (which originates in the vaginal wall). These further contribute to the sphincteric unit in women. Unlike the relative stability and immobility of the male external sphincter, the female sphincteric unit is most certainly vulnerable to common external forces.

A combination of attributes of the female urethra itself contributes to urinary continence. **Intrinsic properties of the urethral mucosa and urethral wall are an important part of maintaining continence in women. The spongy nature of estrogen-sensitive urethral submucosa enhances the apposition of urethral mucosa, which aids in the creation of an effective watertight seal.** In fact, it has been estimated that up to 30% of the forces responsible for continence are derived from this seal (Raz et al, 1972).

Surrounding musculofascial elements further support continence mechanisms in women. **A strong muscular backing (anterior vaginal wall) provides posterior support and additional compression of the midurethra.** Laxity in vaginal support can result in anterior vaginal prolapse and a shearing effect in the continence zone, particularly if anterior ligamentous support at the

proximal urethra (pubourethral ligaments) is intact. **Indeed fixation of the urethra by ligamentous support (pubourethral ligaments) normally minimizes movement of the proximal urethra, further contributing to continence by helping to prevent abdominal forces to be transmitted to the remainder of the urethra.** The urethropelvic ligaments further anchor the urethra to the tendinous arc bilaterally. It is the combined effect of these extraurethral forces, intrinsic urethral properties, and muscular elements that promotes continence, and loss of any one, or several in most cases, can result in UI in women.

KEY POINTS: CONTINENCE MECHANISMS OF THE OUTLET IN WOMEN

- External sphincter mechanisms:
 - Circular striated muscle of the external sphincter in the midurethra under pudendal innervation supplies the majority of active midurethral compression by the external sphincter
 - More distally, longitudinal striated muscle arising from the vagina and perineal membrane contribute to sphincteric forces
- Urethral attributes:
 - Mucosa of urethral wall tends to adhere to itself
 - Spongy, vascular nature of urethral submucosal layer promotes apposition of the urethral wall
- Surrounding support structures:
 - Anterior vaginal wall provides firm posterior support of the urethra allowing compression of the midurethra
 - Fixation of the midurethra anteriorly by the pubourethral ligaments helps prevent transmission of intra-abdominal forces to the remainder of the urethra
 - Further anchoring of the urethra laterally to the arcus tendineus is provided by the urethropelvic ligaments

PATHOPHYSIOLOGY OF URINARY INCONTINENCE: GENERAL PRINCIPLES

Factors Affecting Bladder Storage

UI resulting from bladder dysfunction is induced by a variety of neurologic, iatrogenic, and common demographic risk factors. **Any neurologic process interrupting the normal suprapontine inhibition of the pontine micturition center may result in neurogenic detrusor overactivity (NDO) and cause UII.** CVAs, multiple sclerosis, and Parkinson disease are among the more common neurologic processes that might result in UII. DM, even early in diagnosis, has been associated with NDO and UII. Obstruction resulting from anti-incontinence surgery in women can lead to de novo UII secondary to induced detrusor overactivity (DO). In men, BOO induced by prostatic enlargement (or other obstructive process) can be associated with DO and resultant UII.

Poor emptying from detrusor underactivity or detrusor areflexia (causing overflow incontinence) might also cause UI. This type of detrusor dysfunction is common with neurologic diseases affecting the lumbosacral cord or conus medullaris. Systemic diseases, which can result in peripheral neuropathies such as diabetes, tabes dorsalis, and alcoholism, can similarly cause overflow incontinence. So whereas early in the disease process DM can lead to UII, later in the process sensation can be altered as can detrusor contractility, resulting in impaired bladder emptying, UTIs, and UI. Radical pelvic surgeries (i.e., radical hysterectomy, abdominoperineal resection) can also result in significant, sometime permanent, neurogenic detrusor dysfunction leading to urinary retention and overflow incontinence. Pelvic external beam radiation (commonly used in the treatment of prostate cancer and other pelvic malignancies) can alter bladder compliance, increase detrusor leak point pressure, and contribute to UI.

Factors Affecting Sphincteric Function

The most common causes of **intrinsic sphincteric deficiency (ISD)** are iatrogenic, although, less commonly, neurologic disease can directly impact sphincter function. Traumatic or vascular injury to the lumbosacral cord can impair sphincter function and can result in ISD (Gomelsky et al, 2003). Multiple systems atrophy typically results in loss of intrinsic sphincteric function in men and a high likelihood ($\geq 20\%$) of UI following TURP in men who are considering this surgery. Other processes such as traumatic cervical or upper thoracic spinal cord injury can cause **detrusor sphincter dyssynergia**, creating impaired bladder emptying and UI, particularly when coupled with NDO. Medications used purposely to enhance voiding (α -blockers) can reduce outlet resistance sufficiently to cause leakage in vulnerable patients. Any medication with either α -antagonistic properties or skeletal muscle relaxant properties can also cause UI by inhibiting outlet resistance.

In women, urethral surgery or anti-incontinence surgery can lead to urethral scarring, periurethral fibrosis, and ISD. The likelihood of ISD appears to increase with an increased number of failed surgeries previously. Advanced prolapse surgery performed without concomitant treatment of the bladder outlet appears to result in an increased likelihood of postoperative UI. This appears to be true of both abdominal sacrocolpopexy and vaginal surgery for significant anterior prolapse (Brubaker et al, 2008; Wei et al, 2012). Still, the risks of incontinence surgery, and the reality that some patients who never would have developed UI (and thus are overtreated) must be weighed against the risk of needing future surgery or the impairment of QoL associated with ongoing leakage.

Labor and delivery can also impact sphincter function in women. **Prolonged labor, third-degree lacerations, large birth weight, multiparity, and forceps deliveries are all aspects of labor and delivery that have been associated with sphincteric dysfunction.** The mechanisms by which labor appears to result in UI include direct injury to ligamentous/fascial support, ischemic injury to the pelvic floor as a result of prolonged compression, pelvic or pudendal denervation induced by compression, and direct genitourinary injury. This finding is further corroborated by the study of women followed for decades after cesarean section compared to women who had a single vaginal delivery. Twenty years following delivery, women who underwent vaginal delivery are more likely to experience MUI, SUI, and UUI, and are more likely to report severe forms of UI (Gyhagen et al, 2013).

RP, the most common surgical cause of incontinence in men, generally causes leakage via a direct impairment of sphincter function. Among incontinent men studied urodynamically, ISD is the predominant finding in approximately 70%, whereas DO and altered compliance are less common causes, although they may contribute to the condition in more than 30% of cases (Dubbelman et al, 2012). It is clear, however, that the finding of DO is common among men following RP (more than 50% of men 3 years following RP), regardless of the presence of UI (Song et al, 2010). Following RP, decreases in functional urethral length (64%) and maximum urethral closure pressure (MUCP, 41%) have been noted. In this regard, higher baseline MUCP has been associated with earlier urinary control and lower likelihood of postprostatectomy incontinence (PPI) (Dubbelman et al, 2012). Although the approach of RP (open vs. robotic) does not appear to affect greatly the risk of ISD, preservation of the bladder neck and, in particular, nerve sparing for both open and robotic approaches to RP seems to hasten the recovery of continence and to lower the overall likelihood of PPI (Campodonico and Manuputty, 2012; Srivastava et al, 2013).

PATHOPHYSIOLOGY OF STRESS URINARY INCONTINENCE IN WOMEN

Original theories explaining the pathophysiology of UI in women focused on the descent of the proximal urethra and bladder neck, and the implications of moving away from an intra-abdominal location with anterior pelvic prolapse. It was believed that as the

urethra became hypermobile, intraperitoneal forces could no longer constrict the urethra and incontinence resulted (Enhörning, 1961). The pressure transmission theory was the basis of several effective operations (i.e., Marshall-Marchetti-Krantz and Burch colposuspension) designed to restore the urethra to its normal anatomic location.

Loss of Urethral Support

Gradually the understanding of the urethral support mechanisms and causative factors for SUI evolved. It became clear that urethral support emanated from the endopelvic fascia and was enhanced by anterior support (pubourethral ligament) and posterior support (vaginal wall), all of which normally prevent excessive urethral mobility. Proponents of the current theory thought it best to explain incontinence resulting from urethral hypermobility as the “hammock hypothesis,” based on the work of John DeLancey (DeLancey, 1994). This theory suggests that posterior musculo-fascial support of the urethra from the anterior vaginal wall itself and extending laterally from the vagina to the levator ani and arcus tendineus fascia pelvis contribute to the maintenance of continence seen at times of increases in intra-abdominal pressure (Figs. 74-9 and 74-10). It is compression of the urethra against this firm posterior backing (hammock) that enables the urethra to prevent urinary loss with stress maneuvers. Loss of backing from this musculo-fascial support leads to incontinence because of an inability to compress the urethra, particularly if combined with intact anterior support (creating a shearing effect) and loss of compressive sphincteric forces (Mostwin et al, 1995). Hence this theory suggests that repositioning the urethra, previously

Figure 74-9. Structures involved in urethral support drawn from dissection and three-dimensional reconstruction made from serial sections. Note the connection of the endopelvic fascia and the vaginal wall that lies under the urethra to the arcus tendineus fasciae pelvis and its connection to the levator ani muscle.

Figure 74-10. Lateral view of the pelvic floor with urethra, vagina, and fascial tissues transected at the level of the vesical neck drawn from three-dimensional reconstruction, indicating compression of the urethra by downward force (arrow) against supportive tissues indicating the influence of abdominal pressure on urethra.

considered to be essential, is not necessarily essential to restoring continence in women who leak with SUI. The essential element to restoring continence, then, rests with restoring the layer of support to the posterior urethra and therefore allowing the urethra to be compressed adequately (DeLancey, 1997).

Petros and Ulmsten (1990) proposed an additional explanation for both stress and urge incontinence. The “integral theory” pinpoints the site of the maximal continence zone in the midurethra at the pubourethral ligaments. During times of bladder storage, anterior forces from the pubococcygeus muscle pull the vagina up against the pubourethral ligament to close the urethra. Additionally, backward forces stretch the vagina and bladder neck in a plane around the pubourethral ligament to allow proximal urethral closure (Petros and Skilling, 2001; Petros and Woodman, 2008). The authors contend that laxity of these forces secondary to connective tissue damage leads to the loss of urine with stress and, further, that muscular forces stretching the vaginal membrane against the ligaments activate stretch receptors causing them to fire prematurely. This last event is thought to contribute to urinary urgency and UUI. The concept of midurethral tension-free sling procedures to treat symptomatic SUI was largely based on treating the anatomic deficiencies proposed by Petros and Ulmsten (1990) in their discussion of the integral theory.

Intrinsic Sphincteric Deficiency

Despite the breakthrough in understanding urethral anatomy, function, and support, it remained clear that even with extensive pelvic relaxation and urethral hypermobility, some women were completely continent. More importantly, some women with no hypermobility had fairly severe SUI, particularly those with scarred urethras or certain types of neurogenic disease. The concept of intrinsic sphincteric deficiency (ISD) was introduced in the urologic literature by McGuire and Lytton (1978) in their initial description of the use of autologous fascial slings for patients with SUI resulting from absent or poor urethral function, typically secondary to previous urethral surgeries. In this landmark article, the authors noted significant improvements in the vast majority of patients with severe urethral dysfunction (diagnosed urodynamically) treated by pubovaginal sling, without apparent obstruction in early assessment. Blaivas and Olsson further characterized ISD later (Blaivas and Olsson, 1988) as type III UI to distinguish it from forms of incontinence involving urethral mobility. ISD implies the sphincter activity itself is dysfunctional, whether because of a neural or a structural problem. Patients with ISD have classically been described as having a “pipe stem” urethra, meaning a fixed urethra with little intrinsic closure function. This finding may result from previous surgery and is typically iatrogenic in some way. Subtler forms of ISD, which typically coexist with the finding of urethral hypermobility, are more commonly found and are likely responsible for most forms of SUI. ISD in this setting may be secondary to ischemic injury (birth or other trauma) or other forms of progressive pudendal nerve damage.

ISD was historically identified urodynamically using the concept of VLPP (McGuire et al, 1996). VLPP testing describes the abdominal pressure required to cause urethral incontinence. VLPP measurement cannot be made in the presence of a detrusor contraction or altered bladder compliance. Low VLPP (less than 60 cm water) has been associated with ISD, and this has been used in the past to dictate specific treatments for ISD, such as bulking agents or pubovaginal sling. Both of these treatments may address sphincteric abnormalities and thus were presumed to be more appropriate treatment selections for patients without hypermobility. Our current understanding is that most forms of SUI likely involve some degree of ISD, even if urethral hypermobility is present. This fact underlies the finding that even among patients with hypermobility, treatments such as pubovaginal sling, midurethral sling, and even bulking agents appear to have reasonable efficacy (Blaivas and Chaikin, 2011). It is clear, however, that the reverse is untrue—that treatments aimed specifically at the correction of hypermobility may be less helpful in the presence of severe ISD and limited

mobility. It is for this reason that Burch colposuspension and various needle suspension procedures, for example, have limited usefulness in the treatment of ISD, particularly in the setting of a fixed urethra.

KEY POINTS: THEORIES ON THE PATHOPHYSIOLOGY OF STRESS URINARY INCONTINENCE IN WOMEN

- **Pressure transmission theory**—proposes that descent of the urethra from its protected intraperitoneal position increases the forces placed on more distal urethral continence mechanisms and promotes SUI. Supported by Enhorning (1961) and others, these theories contend that the proximal urethra functionally becomes contiguous with the bladder and, as such, transmission of intra-abdominal forces is placed directly on the urethra. More distal sphincteric mechanisms may not adequately protect against incontinence.
- **Hammock hypothesis**—proposed by DeLancey (1994). Suggests that the urethra is not truly in an intraperitoneal position, rather that firm posterior and lateral support allows compression of the urethra at times of increased intra-abdominal pressure, when combined with active midurethral sphincteric mechanisms. Loss of this support permits the development of SUI. This theory combines elements of previous theories on urethral hypermobility into a more cohesive, anatomically based explanation.
- **Integral theory**—proposed by Petros and Ulmsten (1990). Suggests that both urge and SUI are caused by laxity in the vaginal wall itself and/or surrounding structures (such as pubourethral ligaments). Stretch receptors in the bladder neck, activated at times of increased abdominal pressure with urine deposition in the proximal urethra/bladder neck, are proposed to contribute to urgency incontinence.

PATHOPHYSIOLOGY OF INSENSIBLE INCONTINENCE

Although in most instances women will be able to discern when urine loss occurs, in other cases the timing of incontinence may be unclear. Particularly when incontinence cannot be demonstrated on examination, or cannot be discerned from a thorough history, urodynamic studies and other diagnostic tests might help to determine the cause of leakage. In most cases, the common types of incontinence will still be responsible even if urine loss is insensible, such as sphincteric deficiency or detrusor overactivity incontinence. Other less common causes, however, must be considered, particularly when standard nonoperative measures fail to improve the symptom. Other causes such as urethral diverticula (typically postvoid urine loss), ectopic ureter (typically continuous urine loss), and overflow incontinence (typically small-volume frequent urine loss, urinary frequency, and small volume voids) should be considered. Although urodynamics should identify overflow incontinence, it may miss the other sources, and it may be nondiagnostic in a relatively frequent number of cases (Brucker et al, 2013). Thus in unique circumstances, pelvic MRI (to identify suspected urethral diverticula) and upper tract studies (to identify ureteral ectopy) should be considered in the evaluation of women with insensible urine loss.

PATHOPHYSIOLOGY OF PELVIC ORGAN PROLAPSE

Pelvic support defects are similar to hernias in that they have disruptions in the continuity of their supporting connective tissue (Shull, 1999). However, with the exception of enteroceles, POP is not usually associated with protrusions of the peritoneal sac containing intra-abdominal materials.

Normal pelvic support mechanisms can be separated into three levels, as eloquently described in a cadaver dissection study by John DeLancey (1992) (Fig. 74-11). The upper third of the vagina

Figure 74-11. Levels of support, as described by DeLancey (1992). In level I, the paracolpium suspends the vagina from the lateral pelvic walls. In level II, the vagina is attached to the arcus tendineus of the pelvic fascia and superior fascia of the levator ani muscles. The vagina's lower third fuses with the perineal membrane, levator ani muscles, and perineal body (level III).

Figure 74-12. The cardinal and uterosacral ligaments provide support to the cervix and indirectly to the bladder base. The retropubic, vesicovaginal, and rectovaginal spaces are seen at the level of the cervix. (Modified from Raz S, Stothers L, Chopra A. Vaginal reconstructive surgery for incontinence and prolapse. In: Walsh PC, Retik AB, Vaughan Jr ED, et al, editors. Campbell's urology. 7th ed. Philadelphia: Saunders; 1998. p. 1059–94.)

(level I) is suspended by a continuation of the cardinal ligament known as the paracolpium or the uterosacral ligament/cardinal ligament complex. Level I support suspends the uterus and upper vagina to the sacrum and lateral pelvic sidewall. Level II support includes the paravaginal attachments of the middle third of the vagina laterally to the superior fascia of the levator ani muscle and the arcus tendineus fascia pelvis (Fig. 74-12). Loss of level II support contributes to anterior vaginal wall prolapse/cystocele. The vagina's

lower third fuses with the perineal membrane, levator ani muscles (superficial and deep perineal muscles), and perineal body (level III). Loss of level III support anteriorly results in urethral hypermobility, whereas loss of posterior level III support results in a distal rectocele or perineal descent. According to DeLancey, the paracolpium's vertical fibers in level I form the critical factor that differentiates vaginal eversion from posthysterectomy cystocele, rectocele, or enterocele in which the vaginal apex remains well suspended. Enteroceles are often an asymptomatic consequence of vaginal vault prolapse in that the small bowel simply fills the space previously occupied by the uterus. However, when the small bowel enters the cul-de-sac between the vagina and the rectum in a woman with a relatively well-supported vaginal apex, severe defecatory dysfunction and straining may occur.

Cystoceles have classically been characterized as either those with a central defect (weakness in the midline perivesical fascia) and those with a lateral defect (those with defects in lateral vaginal attachments resulting in paravaginal defects (Shull and Baden, 1989). In all likelihood, the majority of cystocele defects are a combination of both defects. Of note, the loss of apical support (level I) is highly correlated with the development of high-stage cystoceles, and the identification of apical prolapse is crucial in optimizing cystocele management. Rooney and colleagues (2006) used POPQ measurements and found that high-stage cystocele defects are invariably associated with apical prolapse. This fact underlies the high failure rate of anterior colporrhaphy in the treatment of high-stage anterior POP, because the apical defect is essentially ignored. In fact, in a study of Medicare claims by Eilber and colleagues (2013) isolated cystocele repairs were found to have a 20% reoperation rate during a period of 10 years. This number was reduced to 11% when the initial cystocele repair was combined with an apical support procedure.

Objectives

General Patterns of Neuropathic Voiding Dysfunction

Disease at or above the Brainstem

Diseases Primarily Involving the Spinal Cord

Disease Distal to the Spinal Cord

Miscellaneous Neurologic Diseases Causing Lower Urinary Tract Dysfunction

Miscellaneous Conditions Definitely, Probably, or Possibly Related to Neuromuscular Dysfunction

Treatment of Neurogenic Lower Urinary Tract Dysfunction: Overview

OBJECTIVES

The first part of this chapter is a summary of the abnormalities of the micturition cycle produced by different types of neuromuscular disease, injury, or dysfunction. The background material for the central and peripheral factors involved in the pathophysiology and pharmacology of lower urinary tract (LUT) function (and dysfunction) are discussed in Chapters 69 and 79. An understanding of the physiology and pharmacology of normal urinary storage and emptying, as well as the patterns and location of neuropathic insults, will usually, but not always, enable one to easily infer the associated lower tract dysfunction. The second part of the chapter summarizes certain secondary factors that can modify the type of observed LUT dysfunction. These secondary factors are important to consider because they cause persistence of both storage and voiding abnormalities, even after the initial precipitating factors have resolved or have been corrected. The third part of the chapter describes in detail the specific types of LUT dysfunction that occur secondary to the most common categories of neuromuscular disease, injury, or dysfunction. Ideally, in any such discussion, the expected states of the following urodynamic parameters should be described (see Chapter 73 for specific definitions of terms) (Abrams et al, 2003):

- Sensation (normal, absent, impaired)
- Detrusor activity (normal, overactive, areflexic, impaired contractility)
- Detrusor compliance (normal, decreased, increased)
- Smooth sphincter activity (synergic, dyssynergic)
- Striated sphincter activity (synergic, dyssynergic, bradykinetic, impaired voluntary control, fixed tone)

Table 75-1 is a summary of many of these dysfunctions, grouped by the status of the aforementioned urodynamic parameters and the most common type of abnormal pattern resulting from a given disease or injury. This abbreviated classification is not meant to be all-inclusive but to simply indicate that, for the most part, an individual with a specific neurologic abnormality and subsequent LUT dysfunction will typically have the type of dysfunction listed.

The chapter concludes with a general consideration of the principles that should guide the selection of therapeutic interventions for the types of dysfunctions considered. Other chapters cover in detail the individual therapies and their potential consequences. The types of LUT dysfunction in the pediatric age group and their management are specifically covered in Chapter 142.

As an apology to others in the field whose works have not been specifically cited or have not been cited as frequently as they could have been, please note that citations have generally not been chosen, except where noted, because of initial publication or origi-

nal thinking on a particular subject but primarily because of their review or informational content.

GENERAL PATTERNS OF NEUROPATHIC VOIDING DYSFUNCTION

In general, discrete neurologic lesions affect the filling and storage and the emptying and voiding phases of LUT function in a relatively consistent manner. This nature of the impact is dependent on (1) the area(s) of the nervous system affected; (2) the physiologic function(s) and the contents and location of the area(s) affected; and (3) whether the lesion or process is destructive, inflammatory, or irritative. It is important to note that the acute dysfunction produced may, for a variety of reasons, be different from the chronic one.

KEY POINT: LESIONS ABOVE THE BRAINSTEM

- Neurologic lesions above the brainstem (with rare exceptions) that have an impact on micturition typically result in involuntary bladder contractions (detrusor overactivity) with coordinated sphincter function (smooth and striated sphincter synergy). Sensation and voluntary striated sphincter function are usually preserved, but sensation may be deficient or delayed. Detrusor areflexia may, however, occur, either initially or as a permanent dysfunction. Urinary incontinence may occur owing to the detrusor overactivity.

KEY POINT: COMPLETE SPINAL CORD LESIONS FROM SPINAL CORD LEVEL T6 TO S2

- After recovering from a period of spinal shock, patients with complete lesions of the spinal cord between spinal cord level T6 and S2 usually exhibit absent sensation, involuntary bladder contractions (detrusor overactivity), and smooth sphincter synergy, but striated sphincter dyssynergia. In addition, patients with lesions above spinal cord level T6 may experience smooth sphincter dyssynergia and autonomic hyperreflexia. Incontinence may occur owing to detrusor overactivity; however, the outlet obstruction resulting from striated sphincter dyssynergia can also cause urinary retention and overflow incontinence.

TABLE 75-1 Most Common Patterns of Voiding Dysfunction Seen with Various Types of Neurologic Disease or Injury*

DISORDER	DETRUSOR ACTIVITY	COMPLIANCE	SMOOTH SPHINCTER	STRIATED SPHINCTER	OTHER
Cerebrovascular accident	Ov	N	S ±VC	S	There may be decreased sensation of lower urinary tract events.
Brain tumor	Ov	N	S	S	There may be decreased sensation of lower urinary tract events.
Cerebral palsy	Ov	N	S	S D (25% of those with detrusor overactivity) ±VC	
Parkinson disease	Ov I	N	S	S Bradykinesia	
Multiple system atrophy	Ov I	N ↓	Op	S	Striated sphincter may exhibit denervation.
Multiple sclerosis	Ov	N	S	S D (30%-65%)	Dyssynergia figures refer to percentage of those with detrusor activity.
Spinal cord injury Suprasacral	Ov	N	S	D	Smooth sphincter may be dyssynergic if lesion is above T7.
Sacral	A	N ↓ (may develop)	CNR Op (may develop)	F	
Autonomic hyperreflexia	Ov	N	D	D	
Myelodysplasia	A	N O	Op ↓ (may develop)	F	Findings vary widely in different series. Striated sphincter commonly shows some evidence of denervation.
Tabes, pernicious anemia	I A	N ↑	S	S	Primary problem is loss of sensation. Detrusor may become decompensated secondary to overdistention.
Disk disease	A	N	CNR	S	Striated sphincter may show evidence of denervation and fixed tone.
Radical pelvic surgery	I A	↓ N	Op	F	
Diabetes	I A Ov	N ↑	S	S	Sensory loss contributes, but there is a motor neuropathy as well.

Compliance: N, normal; ↓, decreased; ↑, increased.

Detrusor activity: A, areflexia; I, impaired; Ov, overactive.

Smooth sphincter: CNR, competent, nonrelaxing; D, dyssynergic; Op, open, incompetent at rest; S, synergic.

Striated sphincter: D, dyssynergic; F, fixed tone; S, synergic; ±VC, voluntary control may be impaired.

*See chapter content for percentages of patients with dysfunction.

KEY POINT: TRAUMA OR DISEASE BELOW SPINAL CORD LEVEL S2

- Patients with significant nerve root trauma or injury or disease below spinal cord level S2 typically do not manifest involuntary bladder contractions. After the period of spinal shock resolves, persistent detrusor areflexia is the rule. Various forms of decreased compliance during filling (usually resulting from bladder wall fibrosis) may occur and will depend on the type and extent of neurologic insult. An open smooth sphincter area may result, but whether this is caused by sympathetic or parasympathetic decentralization or defunctionalization (or both or neither) has never been determined. Various types of striated sphincter dysfunction may occur, but commonly an injury in this area is associated with a residual resting sphincter tone (not the same as dys-synergia) and striated sphincter activity is not under voluntary control.

KEY POINT: INTERRUPTION OF PERIPHERAL REFLEX ARC

- Processes that affect or interrupt the peripheral reflex arc (coordination among spine, bladder, and urethra) may cause storage or emptying dysfunctions that resemble those seen after distal spinal cord or nerve root injury. Detrusor areflexia often develops, and low compliance may result. The smooth sphincter may be relatively incompetent, and the striated sphincter may exhibit fixed residual tone that does not voluntarily relax. True peripheral neuropathy can be motor or sensory, and, at least initially, the usual sequelae can be expected.

Plasticity

When engaging in a discussion of the nervous system and the structures it innervates, *plasticity* refers to the inherent capacity to undergo structural and functional modification. These induced changes can be reflected on a number of levels: structural, metabolic, and neurologic. In addition, the neurologic changes can then be reflected on a number of levels: morphologic, neurochemical, electrical, and organizational. Each of these changes can be studied at a variety of different levels, from investigation of the end product (e.g., the clinical manifestations) to exploration of the initial molecular correlates and the factors that induce or affect them. The chronic clinical manifestations that we associate with a particular voiding dysfunction may in fact be the ultimate results of the phenomena that fall under the rubric “plasticity.” Up to a certain point the changes may be reversible, but after a certain point they may not be. Thus plasticity may account for the persistence of clinical symptoms after the initial stimulus for dysfunction has been eliminated or corrected.

A more detailed explanation of plasticity as it applies to the neuromuscular dysfunction of the LUT can be found on the Expert Consult website.

DISEASE AT OR ABOVE THE BRAINSTEM**Cerebrovascular Disease****Cerebrovascular Accident (Stroke)**

Cerebrovascular accident (CVA) is a common cause of death and one of the most common causes of disability in the world. CVA is the most devastating manifestation of cerebrovascular disease, with an annual incidence in the United States that has been cited as approximately 795,000 (www.strokecenter.org) and 15 million

worldwide (www.strokecenter.org). Approximately one quarter to one third of CVAs are fatal, and another third necessitate long-term nursing care ([Marinkovic and Badlani, 2001](#)). The prevalence of stroke in persons older than 65 years has been cited as approximately 60 in 1000, and in persons 75 years of age and older, 95 per 1000 ([Khan et al, 1990](#); [Public health and aging, 2003](#)). [Wyndaele and colleagues \(2005, 2009\)](#) estimated that 1 in 200 individuals will sustain a CVA. Although CVA is the third leading cause of death in the United States ([Marinkovic and Badlani, 2001](#)), approximately 75% of stroke victims survive ([Blaivas et al, 1998a](#)). Of the survivors, only 10% are unimpaired, whereas 40% have mild residual effects, 40% have significant disability, and 10% require institutionalization ([Arunable and Badlani, 1993](#)). Thrombosis, occlusion, and hemorrhage are the most common causes of stroke, leading to ischemia and infarction of variably sized areas in the brain, usually around the internal capsule. [Marinkovic and Badlani \(2001\)](#) cite evidence that arterial occlusion is found in 80% of patients.

After an initial acute CVA, urinary retention from detrusor areflexia often occurs. The neurophysiology of this “cerebral shock” is unclear. After a variable degree of recovery from the neurologic lesion, a fixed deficit may become apparent over a few weeks or months. The most common long-term expression of LUT dysfunction after CVA is phasic detrusor overactivity ([Wein and Barrett, 1988](#); [Khan et al, 1990](#); [Fowler, 1999](#); [Wyndaele et al, 2005](#)). Sensation is variable but most typically intact, and thus the patient has urinary urgency and frequency with detrusor overactivity. The appropriate response to detrusor overactivity is to try to inhibit the involuntary bladder contraction by voluntarily and forcefully contracting the striated sphincter. If this can be accomplished, only urgency and frequency result; if not, the result is urgency urinary incontinence.

The exact acute and chronic incidence of any voiding dysfunction after CVA is difficult to cull from the literature. The cited prevalence of urinary incontinence ranges from 32% to 79% on hospital admission for CVA, 25% to 28% on discharge, and 12% to 19% several months later ([Brittain et al, 1998](#)). Based on their experience and that of others, [Sakakibara and associates \(1999\)](#) estimate that some LUT dysfunction occurs in 20% to 50% of patients with focal brain lesions from tumor and CVA. They cite nocturnal frequency as the most common manifestation, affecting 36% of their patients. Urgency urinary incontinence occurred in 29%, “voiding difficulty” in 25%, urgency without incontinence in 25%, diurnal frequency in 13%, and enuresis in 6%. Acute urinary retention occurred in only 6%. [Fowler \(1999\)](#) cited studies showing that the presence of urinary incontinence within 7 days of a stroke is a more powerful prognostic indicator for poor survival and functional dependence than a depressed level of consciousness. [Cariballa \(2003\)](#) found that urinary incontinence at admission had a hazard ratio of 2.8 as a predictor of death from CVA at 3 months. Stroke patients who were incontinent had an increased risk of infectious complications and were malnourished, possible confounders of the increased death risk. [Patel and colleagues \(2001\)](#) reported that urinary incontinence was associated with age older than 75 years, dysphagia, visual field defect, and motor weakness. Certain specific types of strokes also appear to be associated with unusual forms of incontinence. Lenticulocapsular strokes have been noted to be associated with incontinence. Fifty-two percent of patients with strokes in this area of the brain demonstrated post-stroke emotional incontinence, which was not related to other aspects of stroke or gender ([Kim, 2002](#)). The prevalence of urinary and fecal incontinence after hemispheric vascular accident has ranged from 21% to 56% in earlier studies. Urinary incontinence associated with fecal incontinence is the most prevalent condition on admission to rehabilitation units after a vascular event, being prevalent in approximately 33% of patients. Isolated urinary incontinence follows at a rate of 12% and finally isolated fecal incontinence with 8%. At the completion of rehabilitation, combined fecal and urinary incontinence decreases to 15%, isolated urinary incontinence to 8%, and isolated fecal incontinence to approximately 5%. The most prevalent form of urinary incontinence is impaired awareness (insensate or delayed awareness of voiding

Perhaps the most obvious changes that occur as a result of plasticity are (1) chronic changes in neural organization of the micturition reflex that occur after complete spinal cord transection above the level of S2 and (2) the changes in peripheral neural organization that occur after damage to or transection of the peripheral parasympathetic innervation of the LUT. Specific details are contained in the relevant sections of this chapter.

What may be less obvious as a phenomenon related to plasticity are many of the changes that occur subsequent to bladder outlet obstruction. The most obvious changes that occur are those related to muscle and collagen content. However, these are themselves initiated by molecular events that ultimately cause increased contractile protein synthesis and hypertrophic bladder tissue growth (Levin et al, 1995). The initial stimulus might be stretch from overdistention (Cheng et al, 1999) or ischemia, likewise from distention (Chen et al, 1996). Compensation of the bladder smooth muscle cells to initially overcome the increased demand associated with obstruction is associated with alterations in the expression and function of many proteins involved in excitation-contraction coupling and active force generation of bladder smooth muscle (Chacko et al, 1999). Although urodynamic studies reflect obstruction, satisfactory emptying is usually preserved. Changes in the composition of the extracellular matrix occur as well, presumably also caused by an initial stretch stimulus. The ratio of type III collagen to type I collagen increases, and the localization of type III collagen changes as well (within some muscle bundles as well as around them) (Macarak and Howard, 1999). The increase in connective tissue could be related to an increase in certain growth factors emanating from the smooth muscle or to a decrease in the activity of certain metabolic pathways contributing to the breakdown of various forms of collagen (Borer et al, 1999). Ischemia, which itself can be caused by obstruction or by atherosclerosis, has also been hypothesized to contribute to remodeling of the extracellular matrix and fibrosis (Azadzoi et al, 1999; Mostwin et al, 2005).

Bladder outlet obstruction has also been postulated to be associated with partial denervation, owing to damage to the intrinsic innervation of the bladder smooth muscle from a combination of pressure and ischemia (Turner and Brading, 1997; Mostwin et al, 2005). With all of these potential adverse changes occurring, it seems almost miraculous that the bladder is able to maintain its function, but it does for variable periods of time under different circumstances. However, there does come a point when the ability to fill and store and empty is adversely affected, but not necessarily to the same extent. Filling and storage changes seem related primarily to (1) changes in the extracellular matrix, leading to decreased compliance, and (2) the appearance of phasic bladder overactivity. This overactivity could be myogenic in origin (caused by partial denervation—see Turner and Brading, 1997), or it could be neurogenic and related to another facet of plasticity. Afferent neuroplasticity mediated by nerve growth factors (NGFs) occurs experimentally in response to bladder outlet obstruction, a phenomenon that is inhibited by autoimmunization against NGF (Steers et al, 1996). The ability to empty can be adversely affected by factors related to neurogenic or myogenic mechanisms. The myogenic mechanisms could include a reversal of the compensatory changes that initially occur (see Chacko et al, 1999) or a breakdown of the structure and function of the proteins that enable the smooth muscle cells to take up, store, and release calcium, affecting the calcium activation of the contractile apparatus (Zderic et al, 1998; Chacko et al, 1999).

Furthermore, these neurogenic changes associated with outflow obstruction may alter the neurotransmitter milieu of the LUT. In a model of fetal sheep bladder outlet obstruction, ligation of the urachus at mid-gestation in fetal sheep for 1 month resulted in a shifting of muscarinic, purinergic, and nitrergic mechanisms normally present during fetal development and growth. With outflow obstruction, bladder hypocontractility was induced and contractile forces decreased during stimulated conditions, consistent with denervation and the possibility of atropine resistance. Normal urothelial exerted negative ionotropic effects (nitric oxide mediated) were also lost after obstruction. In addition, loss of compliance resulted in reduced elasticity in the obstructed bladders, consistent with denervation (Thiruchelvam et al, 2003). At this time, one cannot reverse certain precipitating factors for the initiation of LUT dysfunction, such as spinal cord transection and peripheral nerve injury. Hence the fact that the changes that result from the neuroplasticity induced by these insults are permanent is not surprising. However, **there are instances in which the initiating “cause” of a particular voiding dysfunction can be removed and yet the symptoms do not entirely disappear. This may be another instance in which neuroplasticity is a major factor.** For instance, irritative lower urinary tract symptoms (LUTS) fail to disappear in a certain percent of patients with outlet obstruction who undergo surgical correction. Chai and coworkers (1998) found an increased incidence of a positive ice-water test result in patients with bladder outlet obstruction, indicating the presence of a primitive reflex circuitry capable of mediating an abnormal micturition reflex. Because the ice-water test is mediated by C-afferent fibers, the findings support the hypothesis that bladder outlet obstruction is associated with afferent neuroplasticity, detectable in this case by ice-water cystometry. Furthermore, persistence of this afferent neural plasticity after relief of the obstruction could account for at least a proportion of the symptomatic treatment failures after urodynamically successful outlet reduction.

Vizzard (1999, 2000a, 2000b, 2000c, 2000d) and Qiao and Vizzard (2004) have written prolifically about various aspects of neuroplasticity, specifically on the occurrence and potential role of such changes in altered LUT dysfunction after spinal cord injury (SCI) and irritant-induced cystitis. Changes in spinal cord protein expression from retrogradely transported bladder neurotrophic factors could play a role in the neurochemical, electrophysiologic, and organizational properties of the LUT seen in both of these conditions and could account, in the latter case, for persistence of symptomatic and/or urodynamic abnormalities after the irritating stimulus has been removed (e.g., in patients with interstitial cystitis). Those especially interested in this area should consult Vizzard's articles and associated references.

events), occurring in 12% to 58% of individuals, as compared with pure urge, which occurs in 9% to 42%. This impaired awareness incontinence is a more significant negative prognostic indicator for resolution of symptoms as compared with patients who retain the sensation of urgency (Kovindha et al, 2010; McKenzie and Badlani, 2012).

In a nationwide Danish assessment of patients after acute stroke, at 1 month after the stroke, patients were asked to assess the severity of their urinary symptoms as well as bother related to each symptom. A total of 482 eligible patients were assessed; 94% of patients had had at least one urinary symptom in the prior 2 weeks, with nocturia being the most frequent (76%), followed by urgency (70%) and urinary daytime frequency (59%). Urgency was the symptom associated with the most bother, followed by nocturia and finally frequency. If a patient had at least one symptom, bother was at least 78%. Bother caused by urinary symptoms was associated with severity of lower extremity paresis, as well as use of analgesics. The overall conclusion was that LUTS were very highly prevalent and also had significant impact on overall bother in this population (Tibaek et al, 2008).

Previous descriptions of LUT dysfunction patterns after CVA have overwhelmingly cited detrusor overactivity with coordinated striated and smooth sphincter activity (Kolominsky-Rabas et al, 2003; Wyndaele et al, 2005; Drake et al, 2013). It is difficult to reconcile this with the relatively high rates of urinary incontinence in these patients, despite the probability that a percentage of these patients already had an incontinence problem before the CVA. Tsuchida and coworkers (1983) and Khan and associates (1990) made early significant contributions in this area by correlating the urodynamic and computed tomographic pictures after CVA. They concluded that patients with lesions in only the basal ganglia or thalamus have normal sphincter function. This indicates that these patients could voluntarily contract the striated sphincter and abort or minimize the effect of an abnormal micturition reflex when an impending involuntary contraction was sensed. Most patients with involvement of the cerebral cortex, internal capsule, or both were unable to forcefully contract the striated sphincter under these circumstances. Although the authors and others have called this problem “uninhibited relaxation of the sphincter” (Marinkovic and Badlani, 2001), this term is a misnomer. In actuality, the term implies that a profound abnormality exists in the cerebral to corticospinal circuitry that is necessary for voluntary control of the striated sphincter. In an assessment of 192 stroke patients, of whom 69 had undergone urodynamic evaluation, minor urodynamic differences were noted among patients with strokes in the dominant versus nondominant hemisphere versus bilateral hemispheric strokes. Of the dominant hemispheric stroke patients, 64.2% demonstrated detrusor overactivity; detrusor underactivity was present in 35% of the patients. In contradistinction, nondominant hemispheric stroke resulted in detrusor overactivity in 66% of patients and detrusor underactivity in 33%, whereas of bilateral stroke patients, 60% demonstrated detrusor overactivity and 40% detrusor underactivity. Therefore no significant difference was noted between location of stroke and urodynamic findings (Kim et al, 2010).

In a summary of findings obtained from electrical stimulation, positron emission tomography (PET), and functional magnetic resonance imaging (fMRI), Griffiths (2004) implicated the Barrington nucleus, the so-called M region, as responsible for normal voiding (coordinated striated sphincter relaxation followed by detrusor contraction). His findings indicate that a second region in the pons—the L region—may be responsible for maintaining striated sphincter tone between voids, although the evidence for this is less convincing. Griffiths (1998), studying the results of single-photon emission computer tomography (SPECT) in a group of geriatric patients with established urinary incontinence, found urgency incontinence in approximately 50%; half of these patients had reduced sensation of bladder filling, more pronounced in men than in women. True urgency urinary incontinence with reduced bladder sensation was associated with global underperfusion of the cerebral cortex, specifically on the right side and the frontal areas. Thus, there are two possible mechanisms for the incontinence

associated with involuntary bladder contractions in patients who have sustained a CVA: (1) impaired striated sphincter control and (2) lack of appreciation of bladder filling and impending bladder contraction.

In general, the smooth sphincter is unaffected after CVA and remains synergic. Some authors describe striated sphincter dys-synergia in 5% to 21% of patients who manifest brain disease and voiding dysfunction (Sakakibara et al, 1999); however, this appears to be incompatible with accepted neural circuitry. True detrusor striated sphincter dyssynergia does not occur in this situation, although pseudodyssynergia has been found to occur during urodynamic testing of these patients (Wein and Barrett, 1982). This finding refers to an electromyographic sphincter “flare” during filling cystometry that is secondary to attempted inhibition of an involuntary bladder contraction by voluntary contraction of the striated sphincter. The guarding reflex in these patients usually remains intact (Siroky and Krane, 1982).

Detrusor hypocontractility or areflexia may rarely persist after CVA. The exact incidence of areflexia as a cause of chronic voiding symptoms after CVA is uncertain, but some estimates place it as high as 20% (Arunable and Badlani, 1993). Linsenmeyer and Zorowitz (1992) found that 35% of men who were incontinent after a CVA had involuntary bladder contractions with urodynamic evidence of bladder outlet obstruction and 6% had detrusor areflexia. In comparison, 13% of women in this group had involuntary contraction with a large residual urine volume and 19% had areflexia. Poor flow rates and high residual urine volumes in a man with LUTS before CVA usually indicate prostatic obstruction. However, a full urodynamic evaluation to exclude detrusor overactivity with impaired contractility as a cause of symptoms is advisable before committing such a patient to surgical reduction of bladder outlet obstruction.

KEY POINT: LOWER URINARY TRACT DYSFUNCTION AFTER CEREBROVASCULAR ACCIDENT

- In the functional system of classification (see Chapter 70), the most common type of LUT dysfunction after CVA would be characterized as a failure to store secondary to detrusor overactivity, specifically involuntary bladder contractions. In the International Continence Society (ICS) classification system, the dysfunction would most likely be classified as overactive neurogenic detrusor function, normal sensation, low capacity, normal compliance, and normal urethral closure function during storage; regarding voiding, the description would be normal detrusor activity and normal urethral function, assuming that no anatomic obstruction existed. Treatment, in the absence of coexisting significant bladder obstruction or significantly impaired contractility, is directed at decreasing bladder contractility and increasing bladder capacity (see Table 70-1 and Box 70-3 in Chapter 70).

Because strokes are often a condition sustained by the elderly, the presentation and management of these patients may be more complex owing to preexistent LUT pathology. Although the urinary symptoms may have been manageable before the CVA, they may become significantly worse afterward. As Andrews (1994) noted, other aspects of the brain damage can affect general rehabilitation and control of the LUT dysfunction. These may include cognitive impairment, dysphasia, inappropriate and aggressive behavior, impaired mobility, and low motivation. In addition, the LUT dysfunction may be significantly and adversely affected by treatment regimens that concentrate on detrusor overactivity alone (e.g., anticholinergic or antispasmodic therapy). Vigorous pharmacologic therapy of detrusor overactivity with agents that cross the blood-brain barrier and inhibit M₁ muscarinic receptors may worsen preexisting confusion, disorientation, and other problems of mentation.

The underlying basic mechanisms of bladder overactivity after CVA remain unclear. Experimental models of middle cerebral artery occlusion have been described, followed by reperfusion to simulate the clinical condition (Pehrson et al, 2003). Shimizu and associates (2003) described the development of a rat model involving an electrolytic lesion of the right basal forebrain. After middle cerebral artery occlusion, neural signaling changes seem to involve glutaminergic, dopaminergic, and γ -aminobutyric acid (GABA)-ergic mechanisms (Kanie et al, 2000; Yokoyama et al, 2002). In addition, Fu and coworkers (2004) have shown upregulation of proinflammatory cytokines and the neuronal nitric oxide synthase gene in the spinal cord and bladder after acute vascular injury. Such findings raise interesting theoretic possibilities for central pharmacologic management. Cerebrovascular injury manifesting with suprapontine injury also can result in an alteration of urinary urgency perception, producing symptomatic frequency and urge incontinence. The underlying pathophysiology of this effect may be elimination of cortical ambulatory control of the pontine micturition center (PMC), possibly combined with facilitation of excitatory control. These aberrant signaling pathways may arise from abnormalities in acetylcholine, dopamine, and glutamate regulatory changes with upregulation or downregulation of excitatory and inhibitory pathways resulting in the overactivity associated with diagnosis (Yokoyama et al, 2009).

Brainstem Stroke

Sakakibara and associates (1996d) reported on 39 patients with brainstem stroke, of whom 19 had LUTS. Problems were more common after damage from bleeding than from infarction. The major problems were nocturnal frequency and voiding difficulty in 6, urinary retention in 8, and urinary incontinence in 3. Symptoms did not occur in those with strictly midbrain lesions but occurred in 18% of patients with medullary stroke and in 35% of patients with pontine lesions. Detrusor overactivity was found in 8 of the 11 symptomatic patients who underwent urodynamic evaluation, and low compliance was found in 1 patient. What was interpreted as striated sphincter dyssynergia was reported in 5 of the 11 patients, and what was called uninhibited sphincter relaxation occurred in 3. The authors concluded that lesions of the dorsolateral pons involving the pontine reticular nucleus, reticular formation, and locus ceruleus were mainly responsible for the micturition disturbances in patients with brainstem lesions. Furthermore, the authors felt that these findings corroborated the presence of a PMC in humans, corresponding to the pontine storage and micturition centers reported in animal studies.

Dementia

Dementia is a poorly understood disease complex involving atrophy and the loss of both gray and white matter of the brain, especially in the frontal lobes, causing deficits with memory and the performance of tasks requiring intellectual mentation. Associated conditions include widespread vascular disease, Alzheimer disease, Pick disease, Creutzfeldt-Jakob disease, syphilis, heat trauma, and encephalitis. Alzheimer disease is the principal cause of dementia in the elderly (Wyndaele et al, 2005; Drake, et al, 2013). Although urinary dysfunction does not consistently accompany dementia, when voiding dysfunction occurs the result is typically incontinence. It is difficult to ascertain whether the pathophysiology and considerations are similar to those in the stroke patient or whether the incontinence reflects a situation in which the individual has simply lost the awareness of the desirability of voluntary urinary control. Even if the person has voluntary sphincter control, such individuals may void when and where they please, because impaired mentation fails to dictate why they should not. Such activity may be caused by detrusor overactivity or an otherwise normal, but inappropriately timed, micturition reflex. An accurate estimate of the prevalence of dementia-associated incontinence is confounded by the difficulty in distinguishing this from age-related changes in the bladder and from other concomitant diseases, as

pointed out by Wyndaele and colleagues (2005) and Drake and coworkers (2013), who cite figures of 30% to 100%. Treatment can be difficult and the outcomes frustrating without a desire for improvement. In addition, therapy that inhibits muscarinic brain receptors may be contraindicated in Alzheimer disease if current theories about its cause are valid (cortical cholinergic loss).

Traumatic Brain Injury

Traumatic brain injury has been cited as the most common form of severe neurologic impairment resulting from trauma (Blaivas and Chancellor, 1995a). As with many neurologic insults, there may be an initial period of detrusor areflexia when LUT dysfunction occurs. With lesions above the PMC, detrusor overactivity and coordinated sphincter function are the most frequent manifestations of chronic LUT dysfunction. In patients who have more isolated brainstem injuries with involvement below the PMC, additional findings may include detrusor striated sphincter dyssynergia.

Chua and colleagues assessed 66 males and 18 females within 6 weeks of acute traumatic brain injury. Of these patients, 62% had urinary incontinence on admission, with urinary retention (defined as postvoid residual volume greater than 100 mL) noted in 9.5%. Sixty-two percent required either indwelling catheters or external collecting devices for urinary maintenance. Urinary incontinence was associated with poor functional status and bilateral lesions, whereas urinary retention was more commonly noted in patients with comorbid diabetes mellitus or fecal impaction. After rehabilitation, 36% remained incontinent (Chua et al, 2003).

Brain Tumor

Disturbances of bladder function have been associated with both primary and metastatic brain tumors. When dysfunction results, it is related to the localized area involved rather than to the tumor type. The areas that are most frequently involved with associated micturition dysfunction are the superior aspects of the frontal lobe (Blaivas, 1985). When LUT dysfunction occurs, it usually consists of detrusor overactivity and urinary incontinence. These individuals may have a markedly diminished awareness of all LUT events and, if so, may be totally unable to even attempt suppression of the micturition reflex. In general, smooth and striated sphincters are synergic, whereas pseudodyssynergia may occur during urodynamic testing. In a review of frontal lobe lesions and bladder control, Fowler (1999) cites instances of improvement of micturition symptoms for a period of time after tumor resection, raising the question of whether the phenomenon of tumor-associated bladder overactivity was a positive one (activating some system) rather than a negative one (releasing a system from control). Urinary retention has also been described in patients with space-occupying lesions of the frontal cortex, in the absence of other associated neurologic deficits (Lang et al, 1996). Posterior fossa tumors may be associated with voiding dysfunction (32% to 70%, based on references cited by Fowler, 1999). Retention or difficulty voiding is the rule, with incontinence being a rare finding.

Cerebellar Ataxia

Cerebellar ataxia refers to a group of diseases involving pathologic degeneration of the nervous system, usually involving the cerebellum but with possible extension to the brainstem, spinal cord, and dorsal nerve roots (Leach et al, 1982). Cerebellar involvement often results in poor coordination, depressed deep tendon reflexes (DTRs), dysarthria, dysmetria, and choreiform movements. LUT dysfunction typically manifests with incontinence, usually associated with detrusor overactivity and sphincter synergy. Retention or high postvoid residual urine volume may occur as well. When present, impaired emptying is most commonly caused by detrusor areflexia, but it may also be associated with detrusor striated sphincter dyssynergia, presumably a result of spinal cord

involvement. Sakakibara and associates (1998b) reported micturition symptoms in 184 patients with spinocerebellar degeneration, of whom 29 (15.8%) had stress urinary incontinence. Although 20 of these 29 also had detrusor overactivity, low compliance, and/or elevated residual urine, the remaining 9 had none of these findings. The authors speculated that, in the absence of other findings, spinal lesions affecting the Onuf nucleus and consequently pudendal nerve function were responsible for the development of stress urinary incontinence.

Normal-Pressure Hydrocephalus

Normal-pressure hydrocephalus is a condition of progressive dementia and ataxia occurring in patients with normal cerebrospinal fluid pressure and distended cerebral ventricles, but with no passage of air over the cerebral convexities on pneumoencephalography (Blaivas, 1985). When voiding dysfunction occurs, it is usually incontinence secondary to detrusor overactivity with synergic sphincters.

Cerebral Palsy

Cerebral palsy (CP) is a nonprogressive injury of the brain that typically occurs during the first year of life (but potentially up to 3 years of age) and produces neuromuscular disability and/or specific symptom complexes of cerebral dysfunction. In general, the cause is infection or a period of hypoxia. Affected children exhibit delayed gross motor development, abnormal motor performance, altered muscle tone, abnormal posture, and exaggerated reflexes. **Most children and adults with only CP have urinary control and what seems to be normal storage and emptying.** The actual incidence of LUT dysfunction in the CP population is unclear, because the few available series report findings predominantly in those with LUTS. Andrews (1994) estimates that a third or more of children with CP have urinary symptoms, whereas Roijen and coworkers (2001) surveyed children and adolescents from six rehabilitation centers and cited the prevalence of "primary urinary incontinence" as 23.5%. The most important factors influencing the occurrence of incontinence were spastic tetraplegia and low intellectual capacity. Wyndaele and colleagues (2005) and Drake and coworkers (2013) cite the occurrence of LUT dysfunction as 36%. When an adult with CP has an acute or subacute change in voiding status, however, it is most likely unrelated to CP.

Reid and Borzyskowski (1993) described findings in 27 patients (ages 3 to 20 years) who were referred because of LUT dysfunction. Incontinence (74%), urinary frequency (56%), and urgency (37%) were the most common presenting symptoms, and detrusor overactivity was the most common urodynamic abnormality (87% of those undergoing urodynamics), with 25% of these exhibiting apparent striated sphincter dyssynergia. Mayo (1992) reported on 33 CP patients referred for evaluation of micturition dysfunction, of whom 10 were older than 20 years. Difficulty urinating was the predominant symptom in about half the patients, but half of these also had overactivity and urgency when the bladder was full. The cause of the difficulty in voluntarily initiating micturition was thought to be a problem with relaxing the pelvic floor and not true striated sphincter dyssynergia. Incontinence was the major presenting symptom in the other half, with associated detrusor overactivity in 14 of 16. All patients exhibited normal voiding otherwise. Decreased sensation was reported in 17 of 23 patients younger than 20 years of age and in 4 of 10 older than 20. The more serious manifestations, such as retention, were found only in the adults, prompting the authors to suggest that difficulty urinating may progress in adulthood. In another study of 37 children (21 girls and 16 boys) ranging in age from 1 to 17 undergoing urodynamic as well as urologic assessment, reduced functional bladder capacity was noted in 54%, whereas detrusor overactivity was observed in 35%. Residual volume was increased in 13.5% and diminished bladder compliance was noted in 10.8% of the patients. In this trial, however, approximately one third of patients with CP and urinary tract symptoms were found to have normal urodynamic

findings (Silva et al, 2009). In another assessment of a CP cohort, Richardson and Palmer evaluated 32 children (15 boys and 16 girls) with urodynamics. Social continence was highly associated with larger capacity bladder with lower storage pressures (presumably improved compliance), lack of uninhibited contractions, and coordinated (lack of pseudodyssynergia) sphincter activity. Bladder sensation differed substantially in continent versus incontinent patients. The main difference between continent and incontinent groups appeared to be delayed bladder sensation in the incontinent group (Richardson and Palmer, 2009).

Reid and Borzyskowski (1993) noted that incontinence can be significantly improved in most CP patients and that, in their experience, intellectual delay is not a barrier to successful management. However, the severe degree of mental delay encountered in some of these individuals makes their management very difficult, such that any evaluation or treatment that requires cooperation becomes virtually impossible. **In individuals with CP who exhibit significant dysfunction, the type of damage that one would suspect from the most common urodynamic abnormalities seems to be localized anatomically above the brainstem. Therefore this is most commonly reflected by phasic detrusor overactivity and coordinated sphincters. However, spinal cord damage can occur, and perhaps this accounts for those individuals with CP who seem to have evidence of striated sphincter dyssynergia or of a more distal type of neural axis lesion.**

Parkinson Disease

Parkinson disease (PD) is a neurodegenerative disorder of unknown cause that affects primarily the dopaminergic neurons of the substantia nigra but also heterogeneous populations of neurons in other locations (Lang and Lozano, 1998). The most important site of pathology is the substantia nigra pars compacta, the origin of the dopaminergic nigrostriatal tract to the caudate nucleus and putamen. **Dopamine deficiency in the nigrostriatal pathway accounts for most of the classic clinical motor features of PD, a symptom complex referred to as parkinsonism, the major signs of which are tremor, skeletal rigidity, and bradykinesia.** Other pathways that may contribute to abnormal neural physiology in PD include the corpus striatum, thalamus, periaqueductal gray matter (PAG), and L and M regions of the PMC, as well as the ventral tegmental area (VTA) of the midbrain (Barbalat, 2010). The role of alterations in dopaminergic receptor subtypes has been assessed in animal models of PD. Treatment with dopamine D₂ agonists and D₁ antagonists appears to result in a reduction of bladder capacity in these models. Brusa and colleagues studied a group of 87 patients with mild PD who were evaluated by symptomatic change and urodynamics after administration of selective dopaminergic agents. Use of agents causing central acute D₂ stimulation resulted in a reduction in bladder capacity and worsened detrusor overactivity, as compared with peripheral dopaminergic antagonists (Brusa et al, 2006). Lang and Lozano (1998) compiled an excellent review of conditions causing parkinsonism other than PD and clinical features of these conditions distinguishing them from PD. These other causes consist of (1) multiple system atrophy (MSA) (includes striatonigral degeneration, sporadic olivopontocerebellar atrophy, and Shy-Drager syndrome); (2) progressive supranuclear palsy; (3) cortical-basal ganglionic degeneration; (4) so-called vascular parkinsonism; and (5) Lewy body dementia. **The combination of asymmetry of symptoms and signs, the presence of a resting tremor, and a good response to levodopa best differentiates PD from parkinsonism produced by other causes, although none of these is individually specific for PD (Fowler, 2007).** Wyndaele and colleagues (2005) and Drake and colleagues (2013) endorsed additional criteria that favor MSA as a cause of LUTS rather than PD: (1) urinary symptoms that precede or occur with onset of parkinsonism; (2) presence of urinary incontinence; (3) significant postvoid residual volume; (4) initial erectile dysfunction; and (5) abnormal striated sphincter electromyographic findings. In addition, 5% of patients initially diagnosed with PD are found to have Parkinson-plus syndromes, characterized by early dementia and/or

falls, symmetrical symptoms, wide-based gait, normal eye movements, autonomic dysfunction, and marked disability. These variants tend to have a worse prognosis than does idiopathic PD, and urinary function is not well described in this subgroup of patients (Nutt and Wooten, 2005).

The gold standard for the diagnosis of PD is the neuropathologic examination. In addition to the characteristic pattern of the loss of selected populations of neurons, there is the presence of degenerating ubiquitin-positive neuronal processes or neurites (Lewy neurites) found in all affected brainstem regions. The Lewy body is an intracytoplasmic eosinophilic hyaline inclusion consistently observed in selectively vulnerable neuronal populations. Lewy bodies are not specific to PD and may be found in small numbers in other neurodegenerative disorders. PD affects both sexes roughly equally and the prevalence is cited as 0.3% of the general population and 3% of people older than 65 years (Lang and Lazano, 1998).

Depending on the definition, LUT dysfunction occurs in 35% to 70% of patients with PD (Berger et al, 1990; Sotolongo, 1993; Blaivas et al, 1998a; Wein and Rovner, 1999; Wyndaele et al, 2005). Preexisting detrusor dysfunction or bladder outlet abnormalities may be present, and the symptomatology may be affected by various types of treatment for the primary disease. LUTS is a frequent manifestation of PD. The time from onset of PD to initiation of LUTS in most studies averages 5 years. The most frequent symptoms include nocturia in 86% of patients, followed by frequency in 71% of patients and urgency in 68% of patients. It has been hypothesized that dopamine modulates the normal micturition reflex, and therefore neurogenic degeneration in the nigrostriatal pathway leads to the significant LUT dysfunction associated with PD (Campeau et al, 2011). One early manifestation of PD may be deficient perception of sensory information in visceral neuronal pathways resulting in delayed perception of bladder filling. Studies have demonstrated that the deep brain stimulation used for improvement of moving function in patients with PD may also benefit this sensory perception (Herzog et al, 2006).

When LUT dysfunction does occur, 50% to 75% of the time symptoms consist of urgency, frequency, nocturia, and urgency incontinence. The remainder of patients have obstructive symptoms or a combination of storage and voiding symptoms. The most common urodynamic finding is detrusor overactivity. The pathophysiology of detrusor overactivity most widely proposed (Fowler, 1999) is that the basal ganglia normally have an inhibitory effect on the micturition reflex, which is abolished by the cell loss in the substantia nigra. It is currently unclear whether the dopamine D₁ or D₂ receptor (or both) is primarily responsible. It has been suggested that loss of inhibitory D₁-like receptors causes detrusor overactivity, allowing D₂ receptors to facilitate micturition (Andersson, 2004). The smooth sphincter is synergic. There is some confusatory recording electromyographic interpretation. Sporadic involuntary activity in the striated sphincter during involuntary bladder contraction has been reported in as many as 60% of patients; however, this does not cause obstruction and cannot be termed *true* detrusor sphincter dyssynergia (DSD), which in general does not occur. Pseudodyssynergia may occur, as well as a delay in striated sphincter relaxation (bradykinesia) at the onset of voluntary micturition, both of which can be urodynamically misinterpreted as *true* dyssynergia. Impaired detrusor contractility may also occur, either in the form of low amplitude or poorly sustained contractions or a combination. Detrusor areflexia is relatively uncommon in PD. PET revealed changes in nine patients in brain activation associated with detrusor overactivity, specifically in the periaqueductal gray, supplementary motor area, cerebellar vermis, insula, putamen, and thalamus. The most prominent degree of increased activation was noted in the cerebellum, with no change in pons during detrusor overactivity (Kitta et al, 2006).

It should be noted, however, that many cases of "PD" in the older literature may actually have been MSA, and citations regarding symptoms and urodynamic findings may therefore not be accurate. A good and important example of this is the inference from the publication by Staskin and coworkers (1988)

that transurethral resection of the prostate (TURP) in the patient with PD is associated with a high incidence of urinary incontinence because of poor striated sphincter control. Retrospective interpretation (Fowler, 1999, 2001; Wyndaele et al, 2005; Drake et al, 2013) has shown that these were patients with MSA and not PD and that TURP should not be contraindicated in patients with PD, because external sphincter acontractility is extremely rare in such patients. However, irrespective of similar studies, one must be cautious with such patients, and a complete urodynamic or video-urodynamic evaluation is advisable. Poorly sustained bladder contractions, sometimes with slow sphincter relaxation, should make one less optimistic regarding the results of outlet reduction in the male.

Christmas and coworkers (1988) demonstrated that subcutaneous administration of a dopamine receptor agonist (apomorphine) can reliably and rapidly reverse parkinsonian "off" periods (periods of worsening symptoms mainly caused by the timing of previous medication doses and the unpredictable nature of motor fluctuations). By repeating video-urodynamic studies during the motor improvement after administration of apomorphine, bladder outlet obstruction secondary to benign prostatic obstruction (BPO) may be able to be distinguished from voiding dysfunction secondary to PD. The authors also point out that apomorphine might be useful in such patients who have severe off-phase voiding dysfunction, such as those with disabling nocturnal frequency and incontinence. LUT dysfunction secondary to PD defies routine classification within any system. It manifests mostly with storage failure secondary to bladder overactivity, but detailed urodynamic evaluation is mandatory before any but the simplest and most reversible therapy is initiated. The therapeutic menus (see Table 70-1 and Box 70-3 in Chapter 70) are perfectly applicable, but the disease itself may impose certain limitations on the use of certain treatments (e.g., limited mobility for rapid toilet access, hand control insufficient for clean intermittent catheterization [CIC]). The role of medications used to treat PD and exacerbation of LUTS in these patients has been postulated. Some studies have shown a relationship between the degree of neurologic impairment associated with PD and associated LUTS. Quality of life has been shown to be directly linked to the severity of LUTS, with urinary frequency and nocturia having the most deleterious impact. Overall, in a study of 110 patients, 63 (57.3%) were symptomatic from the urinary tract standpoint. No impact on LUTS was associated with use of levodopa, anticholinergics, or dopamine receptor agonists. Similar symptomatic impact occurred in both genders (Sammour et al, 2009). Bromocriptine may have a role in the exacerbation of urgency in PD patients. In a prospective trial of 8 patients with stable PD, bromocriptine was administered followed by urodynamic and systematic assessment. Urinary urgency was found to be symptomatically exacerbated after bromocriptine administration, and this was accompanied by increased detrusor overactivity. However, there was improvement in bladder emptying associated with enhanced detrusor contractility and decreased bladder outlet resistance (Uchiyama et al, 2009). Animal models of PD have been developed, using injections of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine or 6-hydroxydopamine into the nigrostriatal pathway (Yoshimura et al, 2003; Andersson, 2004; Wyndaele et al, 2005; Drake et al, 2013).

Subthalamic nucleus deep brain stimulation has been shown to be effective for motor symptoms and dyskinesias in patients with moderate to severe PD. Clinical studies have shown that this type of stimulation improves urinary function in these patients by ameliorating bladder sensation and also improving functional bladder capacity. Herzog and colleagues studied 11 patients undergoing deep brain stimulation with PET scans of regional cerebral blood flow. In addition, subjects were studied with urodynamics both with stimulation on and stimulation off. At urodynamic capacity, significant increases in anterior cingulate regional blood flow were noted and were increased when deep brain stimulation was off. At bladder capacity, there was also an increase in lateral frontal cortical blood flow with stimulation off. These results were felt to be indicative of deep brain stimulation improvement of bladder function by the

modulation of afferent bladder information to cortical and subcortical areas (Herzog et al, 2006). Further evidence of the effect of deep brain stimulation on PD was recently reported by Winge and colleagues (Winge and Nielsen, 2012). A cohort of patients received oral medications only and was compared with a group of individuals being treated either with deep brain stimulation or with apomorphine pump for control of symptoms. A total of 170 patients were available, and outcomes reported were symptom scores (International Prostate Symptom Score [IPSS] and Danish Prostate Symptom Score [DanPSS]). There was no significant difference between the treatment groups in terms of overall symptom scores. Bladder symptom score did correlate to the stage of disease progression except for those individuals treated with deep brain stimulation, in whom symptom severity correlated to deep brain stimulation duration. Deep brain stimulation significantly decreased the amount of nocturia patients experienced (Winge and Nielsen, 2012).

Other therapies have been reported for the treatment of LUTS associated with PD. Botulinum toxin has demonstrated benefit in patients with PD; varying the doses of different toxin serotypes has demonstrated improvements in urinary frequency and quality of life as well as incontinence episodes for up to 9 months (Giannantoni et al, 2009; Kulaksizoglu and Parman, 2010). In addition, peripheral intermittent neuromodulation (posterior tibial nerve stimulation) has demonstrated improvements in detrusor overactivity and improved mean cystometric capacity in five of seven patients undergoing intervention (Kabay et al, 2009). Another therapy that has demonstrated some benefit for LUT dysfunction in PD is repetitive transcranial magnetic stimulation (rTMS). In eight patients with advanced PD, this therapy demonstrated temporary improvement in LUTS as well as improvement in bladder capacity and first sensation on cystometric filling. The beneficial effect of this therapy was noted to last for approximately 2 weeks, consistent with findings associated with other temporary forms of neuromodulation (Brusa et al, 2009).

Multiple System Atrophy

MSA results from glial α -synucleinopathy and is a progressive neurodegenerative disease of unknown cause. The symptoms encompass parkinsonism and cerebellar, autonomic (including urinary and erectile problems), and pyramidal cortical dysfunction in a multitude of combinations. The clinical features and the differentiation from PD are nicely described in a consensus statement by Gilman and associates (1999). These investigators advocate a designation of MSA-P if parkinsonian features predominate and one of MSA-C if cerebellar features predominate. Older names such as *striatonigral degeneration*, *sporadic olivopontocerebellar atrophy*, and *Shy-Drager syndrome* (Wein, 2002a, 2002b) should be discarded in favor of these terms.

The neurologic lesions of MSA consist of cell loss and gliosis in widespread areas and occur to a significantly greater degree than with PD. This more diffuse nature of cell loss probably explains why bladder symptoms may occur earlier and be more severe than in PD, and why erectile function may be affected as well (Kirby et al, 1986; Beck et al, 1994; Chandiramani et al, 1997). Affected areas have been identified in the cerebellum, substantia nigra, globus pallidus, caudate, putamen, inferior olives, intermediolateral columns of the spinal cord, and Onuf nucleus. Males and females are equally affected, with the onset in middle age. MSA is usually progressive and associated with a poor prognosis.

Shy-Drager syndrome has been described in the past as characterized clinically by orthostatic hypotension, anhidrosis, and varying degrees of cerebellar and parkinsonian dysfunction. Voiding and erectile dysfunction are common. Some consider this to be late-stage MSA (Chandiramani et al, 1997).

Chandiramani and coworkers (1997) compared the clinical features of 52 patients with probable MSA and 41 patients with PD. Sixty percent of patients with MSA had their urinary symptoms precede or occur with their symptoms of parkinsonism; 94% of patients with PD had been diagnosed for several years before the onset of urinary symptoms. In patients with MSA, urinary

incontinence was a significant complaint in 73%; 19% had only frequency and urgency without incontinence, and 66% had a significant postvoid residual volume (100 to 450 mL). In patients with PD, frequency and urgency were the predominant symptoms in 85%, incontinence was the primary complaint in 15%, and the postvoid residual volume was elevated in only 5 of the 32 patients in whom it was measured. Eleven men with MSA underwent TURP, and 9 of these had deterioration of their urinary incontinence afterward. All 3 women with MSA were incontinent after pelvic floor repair. Five men with PD underwent prostatectomy, and 3 reported a good result. Of 27 men with MSA questioned about erectile function, 93% reported erectile failure, and in 13 of these (48%) the erectile dysfunction preceded the diagnosis of MSA. Seven of the 21 men with PD had erectile failure, but in all of these men the diagnosis of erectile dysfunction followed the diagnosis of PD by 1 to 4 years. The urogenital criteria favoring a diagnosis of MSA (Fowler, 2001) are (1) urinary symptoms that precede or occur with parkinsonism; (2) male erectile dysfunction that precedes or occurs with parkinsonism; (3) urinary incontinence; (4) significant postvoid residual volume; and (5) worsening LUT dysfunction after urologic surgery. Others have reported the progressive nature of LUTS associated with MSA. With time, incontinence and significant postvoid residual volume become more problematic, with steady progression of the condition in all patients (Papatsoris et al, 2008).

The initial urinary symptoms of MSA are urgency, frequency, and urgency incontinence, occurring up to 4 years before the diagnosis is made. As would be expected from the central nervous system (CNS) areas affected, detrusor overactivity is frequently found; however, decreased compliance may also occur, reflecting distal spinal involvement of the locations of the cell bodies of autonomic neurons innervating the LUT. As the disease progresses, difficulty in initiating and maintaining voiding may occur, probably from pontine and sacral cord lesions, and this usually is associated with a poor prognosis. Cystourethrography or video-urodynamic studies may reveal an open bladder neck, and many patients exhibit evidence of striated sphincter denervation on motor unit electromyography. The smooth and striated sphincter abnormalities predispose women to sphincteric incontinence and make prostatectomy hazardous in men. Berger and coworkers (1990) described a useful urodynamic differentiation of what was termed *Shy-Drager syndrome* (probable late-stage MSA) from PD. In general, parkinsonian patients with voiding dysfunction have detrusor overactivity and normal compliance. An open bladder neck was seen only in patients with Shy-Drager syndrome, excluding patients with PD who had had a prostatectomy. Electromyographic evidence of striated sphincter denervation was seen much more commonly in those diagnosed as having Shy-Drager syndrome.

The treatment of significant LUT dysfunction caused by MSA is difficult and seldom satisfactory. Treatment of detrusor overactivity during filling may worsen problems initiating voluntary micturition or worsen impaired contractility during emptying. Patients usually have sphincteric insufficiency; therefore an outlet-reducing procedure is rarely indicated. Conversely, drug treatment for sphincteric incontinence may further worsen emptying problems. In general, the goal in these patients is to facilitate storage, and CIC would often be desirable. Unfortunately, patients with advanced disease often are not candidates for CIC. Some patients do respond well to desmopressin administration for predominant nocturia; however, the majority of the patients do not respond well to antimuscarinic or other types of therapy (Wenning and Stefanova, 2009).

DISEASES PRIMARILY INVOLVING THE SPINAL CORD

Multiple Sclerosis

Multiple sclerosis (MS) is primarily a disease of adults ages 20 to 50 years with a twofold predilection for women. Litwiler and colleagues (1999) detailed prevalence rates for MS as 1 per 1000 Americans, 2 per 1000 northern Europeans, and 20 to 40 per 100,000 first-degree relatives of patients with MS. The World Health

Organization (WHO) in 2008 estimated that 2 to 2.5 million people worldwide had MS (WHO, 2008). Most commonly the age of onset is 30 to 38 years of age for relapsing, remitting, and progressive phases. Common symptoms include optic nerve dysfunction, pyramidal tract abnormalities (hyper-reflexia), ataxia, bowel dysfunction, neurogenic bladder, and bowel and sexual dysfunction. Primary and secondary progressive MS are predominately spinal diseases, and their activity affects LUT function.

Although the cause is not clear, the disease is believed to be immune mediated and is characterized by neural demyelination in the brain and spinal cord; it is characterized, in general, by axonal sparing (Noseworthy et al, 2000). This demyelination causes impairment of saltatory conduction and conduction velocity in axonal pathways, resulting in various neurologic abnormalities that are subject to exacerbation and remission. Lesions, known as *plaques*, range from 1 mm to 4 cm and are scattered throughout the white matter of the nervous system (Chancellor and Blaivas, 1993; Clanet, 2008). The demyelinating process most commonly involves the lateral corticospinal (pyramidal) and reticulospinal columns of the cervical spinal cord, and it is thus not surprising that LUT dysfunction and sphincter dysfunction are so common. Autopsy studies have revealed almost constant evidence of demyelination in the cervical spinal cord, but involvement of the lumbar and sacral cord may occur in approximately 40% and 18%, respectively (Blaivas and Kaplan, 1988). Lesions may also occur in the optic nerve and in the cerebral cortex and midbrain, the latter accounting for the intellectual deterioration and/or euphoria that may accompany physical findings (Kirby, 1994; Noseworthy et al, 2000) in as many as 43% to 65% of patients (Litwiler et al, 1999). A rat model for a demyelinating disease resembling MS has been described using myelin basic protein as an antigen for inducing experimental allergic encephalomyelitis (Mizusawa et al, 2000).

Some patients with MS demonstrate intravesical changes in receptor density and type. In a study of 18 patients with LUTS associated with MS, patients underwent evaluation with urologic assessment and urodynamics. Two groups were identified: one with pronounced neurogenic detrusor overactivity and minimal outflow obstruction, and the second with some degree of neurogenic detrusor overactivity or detrusor hypocontractility during voiding and a high degree of bladder outflow obstruction. Cold-cup biopsies were performed on all patients, and the density of calcitonin gene-related peptide (CGRP)- and substance P (SP)-positive nerve fibers was noted to be higher in the first group, suggesting that denser innervation is present in patients with milder degrees of outflow obstruction and retention of detrusor contractility as compared with individuals without these findings (Radziszewski et al, 2009).

The incidence of LUT dysfunction in MS is related to the disability status. Of patients with MS, 50% to 90% report voiding symptoms at some time; the prevalence of incontinence is cited as 37% to 72% (Wyndaele et al, 2005; Drake et al, 2013). In a comprehensive review of the literature, Litwiler and coworkers (1999) cited symptoms of frequency or urgency in 31% to 85% of patients, incontinence in 37% to 72%, and obstructive symptoms with urinary retention in 2% to 52%. LUT involvement may constitute the sole initial complaint or may be part of the presenting symptom complex in up to 15% of patients, typically with a presentation of acute urinary retention of unknown cause or as an acute onset of urgency and frequency (Wyndaele et al, 2005).

In terms of urodynamic findings, detrusor overactivity is the most common abnormality detected, occurring in 34% to 99% of patients in reported series (Blaivas and Kaplan, 1988; Chancellor and Blaivas, 1993; Sirls et al, 1994; Litwiler et al, 1999). Striated sphincter dyssynergia coexists with overactivity in 30% to 65% of patients. The prevalence of coexistent impaired detrusor contractility or areflexia ranges from 12% to 38% (Wyndaele et al, 2005; Drake et al, 2013), a phenomenon that can considerably complicate treatment efforts. More recent estimates suggest that 62% of patients with MS have neurogenic detrusor overactivity with bladder outlet obstruction, 25% have neurogenic detrusor overactivity with DSD, 20% have detrusor underactivity, and 10% have no initial abnormal urodynamic findings. It is important to note that

the variability and potential multiplicity of lesions associated with MS may prohibit accurate diagnosis based on urodynamics alone (Ukkonen et al, 2004).

In general, the smooth sphincter is synergic. Chancellor and Blaivas (1993) reviewed urodynamic findings in multiple series of patients with MS and voiding dysfunction and cited the incidence of detrusor overactivity with striated sphincter synergia to be 26% to 50% (average, 38%), detrusor overactivity with striated sphincter dyssynergia to be 24% to 46% (average, 29%), and detrusor areflexia to be 19% to 40% (average, 26%). Litwiler and coworkers (1999) report approximately the same ranges in a review of 22 studies. It is also possible to see relative degrees of sphincteric flaccidity caused by MS. Although this finding is relatively rare and occurs in fewer than 15% of patients (Litwiler et al, 1999), it could contribute to and predispose patients to sphincteric incontinence. De Ridder and colleagues (1998) reported weakness of pelvic floor contraction in almost all of the 30 women with MS whom they studied. Spasticity of the pelvic floor was present in all patients with striated sphincter dyssynergia but in none with detrusor overactivity alone. Up to 80% of patients will have neurogenic vesicourethral dysfunction at some point during the course of their disease (Fletcher and Lemack, 2009).

Because sensation is frequently intact in these patients, one must be careful to distinguish urodynamic pseudodyssynergia from true striated sphincter dyssynergia. Blaivas and associates (1981) subcategorized true striated sphincter dyssynergia in patients with MS and identified some varieties that are more worrisome than others. For example, a brief period of striated sphincter dyssynergia during detrusor contraction in a woman with MS may be relatively inconsequential, as long as it does not result in excessive intravesical pressure during voiding, substantial postvoid residual urine volume, or secondary detrusor hypertrophy. However, more sustained episodes of striated sphincter dyssynergia that result in high bladder pressures of long duration are most associated with urologic complications. Giannantoni and colleagues (1998) likewise concluded that there was a significant relationship between the maximum amplitude of the involuntary bladder contractions and upper urinary tract deterioration in their MS population of 116 patients. Chancellor and Blaivas (1993) emphasized what they believed were the most important parameters predisposing patients with MS to significant urologic complications: (1) striated sphincter dyssynergia in men; (2) high detrusor filling pressure; and (3) an indwelling catheter. It is interesting to note that Wyndaele's committee (Wyndaele, 2005; Drake et al, 2013) concluded that progressive neurologic disease in patients with MS rarely causes upper urinary tract damage, even when severe spasticity and disability exist. The reason for this is unknown, but the committee proposed that the situation and concerns with respect to MS were unlike those for SCI.

KEY POINT: MULTIPLE SCLEROSIS

- The most common functional classification applicable to patients with LUT dysfunction secondary to MS would be storage failure secondary to detrusor overactivity. This is commonly complicated by striated sphincter dyssynergia, with varying sequelae based on the patient's ability to empty completely at acceptable voiding pressures. Other abnormalities, and especially combined deficits, are obviously possible.
- Once the dysfunction is broadly characterized, the treatment options should be obvious from the therapeutic menus (see Table 70-1 and Box 70-3 in Chapter 70).

Aggressive and anticipatory medical management can obviate most of the significant complications. Sirls and associates (1994) reported that less than 10% of their patients required surgical intervention resulting from failure of aggressive medical management and that none developed hydronephrosis on such therapy. The

regimens used were (1) medications to decrease detrusor overactivity plus CIC (57%); (2) medications alone (13%); (3) CIC alone (15%); and (4) behavioral therapy. **Caution should be exercised in recommending irreversible therapeutic options, because a significant proportion of patients with MS, both with and without new symptoms, will develop changes in their detrusor compliance and urodynamic pattern (Ciancio et al, 2001).** No factors appear to be predictive of upper tract changes in MS. In a 4-year follow-up of 113 MS patients, 66 underwent both urodynamic and renal ultrasound testing. Eleven of the 66 patients (17%) had abnormal ultrasound findings, with the most significant finding being minor caliectasis of no clinical significance. Neither creatinine nor urodynamic findings were associated with the abnormal renal ultrasound findings (Lemack et al, 2005). Others have noted the lack of predictability of urinary symptoms for disease status, making baseline testing with urodynamics critical to disease assessment and management (Nakipoglu et al, 2009). Surgical intervention for MS appears to be diminishing with improved pharmacologic management and the realization of the alternating neurologic picture of lower urinary dysfunction associated with MS (Ukkonen et al, 2004; Togami et al, 2013).

Physiotherapeutic management has demonstrated success for this condition. In a recent Australian trial with 73 patients with MS, 40 patients were randomized to an individualized bladder rehabilitation program that included baseline assessment (3-day voiding charts, fluid balance, intake restrictions, postvoid residual measurement, and urodynamics). Subsequently, bladder reeducation, pelvic floor exercises, and instruction in techniques for improved bladder emptying and a bowel program were instituted. A nonintervention group served as control. Substantial improvements in all subjective quality-of-life indicators were noted in the intervention group, as compared with the nonintervention group, demonstrating the benefit of a bladder and bowel regimen in this population (Khan et al, 2009).

At present there is no consensus on optimal bladder management for patients with MS, and management is most commonly predicated on symptomatic and urodynamic findings. On the basis of expert consensus, De Ridder and associates (2005) concluded that in early MS, anticholinergics and CIC were considered to be the cornerstones of therapy. For patients with advanced MS (with an Expanded Disability Status Scale [EDSS] score >7), specific guidelines remain lacking. In general, Credé voiding or Valsalva voiding are contraindicated, especially in the presence of DSD. The committee further recommended that indwelling catheters be reserved for patients for whom all other possible treatments have failed. In the approximately 30% of patients with MS using indwelling urinary catheters, the suprapubic route is the preferred route in both men and women. This form of management is considered reasonable for that subpopulation, as long as vigilant long-term follow-up is maintained (De Ridder et al, 2005).

The emerging role of onabotulinum toxin therapy for bladder overactivity related to MS has been recently reported. Detrusor overactivity suppressed with onabotulinum toxin injection can provide social continence and improved quality of life. Stability of response and safety have been reported over treatment periods as long as five cycles. Kennelly and colleagues reported long-term experience with 387 patients with neurogenic detrusor overactivity caused by either MS or SCI and found that 73% to 94% of patients reported incontinence episode reductions of at least 50% depending on treatment cycle assessed (Kennelly et al, 2013).

Spinal Cord Injury

Epidemiology, Morbidity, General Concepts

SCI may occur as a consequence of acts of violence, fracture, or dislocation of the spinal column secondary to motor vehicle collisions, diving accidents or falls, vascular injuries or surgical repairs, infection, disk prolapse, or sudden and/or severe hyperextension from other causes. Altered LUT and sexual function frequently occur secondary to SCI and have a significant impact on quality of life.

SCI patients are at risk urologically for urinary tract infection (UTI), sepsis, upper urinary tract and LUT deterioration, upper urinary tract and LUT calculi, autonomic hyperreflexia (dysreflexia), skin complications, and depression (which can complicate urologic management). Failure to properly address the LUT dysfunction can lead to significant morbidity and mortality. There is great variation in urologic practice regarding initial evaluation, follow-up, and surveillance among spinal injury units (Bycroft et al, 2004), a problem that Boone (2004) properly attributes to a lack of evidence-based decision making.

Complete anatomic transection of the spinal cord is rare, and the degree of neurologic deficit varies with the level and severity of the injury. **Spinal column (bone) segments are numbered by the vertebral level, and these have a different relationship to the spinal cord segmental level at different locations. One must be careful to specify cord or column level when discussing SCI. The sacral spinal cord begins at about spinal column level T12 to L1. The spinal cord terminates in the cauda equina at approximately the spinal column level of L2.** Multiple-level injuries may occur, and, even with a single isolated initial injury, cord damage may not remain confined to a single cord segment and may extend cephalad, caudad, or both.

Stover and Fine (1987) reviewed the epidemiology and other general aspects of SCI. The annual rate was reported as 30 to 32 new SCIs per million persons at risk in the United States; the prevalence was approximately 906 per million. This coincides roughly with the estimate by DeVivo (1997) of approximately 10,000 new cases of SCI in the United States yearly and an estimate of 12,000 per year by Rabchevsky and Smith (2001). More recent estimates concur with these earlier studies (National Spinal Cord Injury Statistical Center, Birmingham, AL. Office of Special Education and Rehabilitative Services, U.S. Department of Education, Washington, DC 2012). The most common mechanisms of injury, as collected by the National Spinal Cord Injury Statistical Center, are motor vehicle accidents (39.2%), violence (14.6%), falls (28.3%), and sports-related injuries (8.2%). Males account for 71% to 81% of patients with SCI. From 1973 to 1979, the average age at injury was 28.7 years, and most injuries occurred between the ages of 16 and 30. However, as the median age of the general population of the United States has increased by approximately 9 years since the mid 1970s, the average age at injury has also steadily increased over time. Since 2005, the average age at injury is 41.0 years. Children constitute 3% to 5% of all patients with SCI (Generao et al, 2004). Stover and Fine (1987) reported that neurologically incomplete quadriplegics constituted the largest group of SCI patients at the time of hospital admission (28%), followed by complete paraplegics (26%), complete quadriplegics (24%), and incomplete paraplegics (18%). Since 2005, the most frequent neurologic category at discharge of persons reported to the database is incomplete tetraplegia (40.8%), followed by complete paraplegia (21.6%), incomplete paraplegia (21.4%), and complete tetraplegia (15.8%). Less than 1% of persons experienced complete neurologic recovery by hospital discharge. The majority of SCIs occur at or above the T12 spinal column (vertebral) level, with injury to one of the eight cervical segments accounting for the patients with tetraplegia and with patients with paraplegia having injury in the thoracic, lumbar, or sacral regions of the spinal cord. SCI is associated with long-term urologic functional compromise. In an assessment of 236 patients with follow-up of mean 24 years, 43% of patients continue to report incontinence at time of follow-up, with paraplegics reporting daily incontinence more frequently than tetraplegics (presumably because of catheter dependence of the latter group). Only 19% of patients used some form of medication for assistance in management of their incontinence. Surprisingly, CIC was associated with higher rates of incontinence than other types of bladder drainage techniques (Hansen et al, 2010).

Although earlier data (Hackler, 1977) indicated that renal disease was the major cause of death, at least in the paraplegic patient, a retrospective study of more than 5000 patients who sustained SCI between 1973 and 1980 revealed that the leading causes of death at that time were pneumonia, septicemia,

pulmonary emboli, heart disease, accidents, and suicide (Stover and Fine, 1987; Soden et al, 2000). These figures seemingly indicate a distinct improvement in the urologic care of these patients. Impaired mobility is commonly noted in the SCI patient and may substantially affect urinary habits and continence (Biering-Sorensen et al, 2004). Urologic phenomena also figure prominently in chronic SCI; approximately 7% of patients will develop an initial kidney stone within 10 years after initial injury. The greatest risk occurs during the first 3 months after injury, and 98% of these stones will be apatite or struvite in composition. There appear to be two specific time frames for stone formation in this population, one being the acute phase associated with immobilization and immobilization hypercalciuria. A more chronic phase stone formation period that usually is associated with chronic catheter management occurs years after injury and predominately involves the LUT (Post and Noreau, 2005).

Controlled and coordinated LUT function depends on an intact neural axis. Bladder contractility and the occurrence of reflex contractions depend on an intact sacral spinal cord and its afferent and efferent connections (see Chapter 69).

KEY POINT: SPINAL CORD INJURY

- In general, complete SCI above the sacral spinal cord but below the area of the sympathetic outflow results in detrusor overactivity, absent sensation below the level of the lesion, smooth sphincter synergy, and striated sphincter dyssynergia. Lesions at or above the spinal cord level of T7 or T8 (the spinal column level of T6) may result in smooth sphincter dyssynergia as well. However, despite the strong correlation between neurologic and urodynamic findings, it is not perfect, and a neurologic examination is no substitute for a urodynamic evaluation in these patients when one is determining risk factors and treatment.

There is an impressive amount of literature that is continuously building on the neurobiology of the spinal cord and its acute and chronic alteration after SCI. A section can be found on the Expert Consult website.

Sexual and reproductive dysfunction in the patient with SCI is a topic that deserves much attention in the overall rehabilitation plan. Pertinent general and specific concepts of sexual and reproductive dysfunction and their normalization in this special group of patients can be found in Chapters 26, 30, and 32. Other excellent reviews on the specifics of sexual function in SCI can be found by Bennett and coworkers (1988), Stone and MacDermott (1989), Smith and Bodner (1993), and Biering-Sorensen and Sonksen (2001), and on infertility by Linsensmeyer and Perkash (1991), Rajaskaran and Monga (1999), and Rutkowski and colleagues (1999).

Spinal Shock

A period of "spinal shock" may be expected after a significant SCI, defined as decreased excitability of spinal cord segments at and below the level of the lesion. There is **absent somatic reflex activity and flaccid muscle paralysis below this level**. Although classic teaching refers to generalized areflexia below the level of the lesion for days to months, Thomas and O'Flynn (1994) confirm that the most peripheral somatic reflexes of the sacral cord segments (the anal and bulbocavernosus reflexes) may never disappear or, if they do, may return within minutes or hours of the injury. However, functions proximal to the level of the injury may be depressed as well (Atkinson and Atkinson, 1996). Although the course of spinal shock is well known, the actual phenomenon remains poorly understood, with few or no recent additions to basic research.

Spinal shock includes a suppression of autonomic activity as well as somatic activity, and the bladder is acontractile and areflexic. Radiologically, the bladder has a smooth contour with no evidence of trabeculation. The bladder neck is usually closed and competent, unless there has been prior surgery or the patient has

sustained a potential thoracolumbar and presumably sympathetic injury (Sullivan and Yalla, 1992). The smooth sphincter mechanism appears to be functional. Some electromyographic activity may be recorded from the striated sphincter, and the maximum urethral closure pressure is lower than normal but still maintained at the level of the external sphincter zone. However, the normal guarding reflex (striated sphincter response during filling) is absent and there is no voluntary control (Fam and Yalla, 1988). Because sphincter tone exists, urinary incontinence usually does not result unless there is gross overdistention with overflow. In evolving lesions, every attempt should be made to preserve as low a bladder storage pressure as possible and to avoid any measures that might impair this. Urinary retention is the rule, and catheterization is necessary to circumvent this problem. Although virtually all would agree that CIC is an excellent and preferred method of management during this period, Lloyd and coworkers (1986) reported their own experience and that of others that indicate no differences in outcome when a small-bore indwelling urethral catheter or suprapubic tube is used at this stage.

If the distal spinal cord is intact but is simply isolated from higher centers, there is usually a return of reflex detrusor contractility. At first, such reflex activity is poorly sustained and produces only low-pressure changes, but the strength and duration of such involuntary contractions typically increase, producing involuntary voiding, usually with incomplete bladder emptying. This return of reflex bladder activity typically manifests with involuntary voiding between catheterizations and occurs along with the recovery of lower extremity deep tendon reflexes (DTRs). Spinal shock usually lasts 6 to 12 weeks in complete suprasacral spinal cord lesions but may last up to 1 or 2 years. It may last a shorter period of time in incomplete suprasacral lesions and only a few days in some.

Suprasacral Spinal Cord Injury

There is no consensus agreement on the neurobiology of the development of reflex bladder contraction in response to bladder distention after suprasacral SCI. de Groat and colleagues (1997) have studied this phenomenon extensively in cats and listed four potential mechanisms for the recovery of such micturition and the development of C-fiber afferent evoked bladder reflexes (see also the description in Chapter 69): (1) elimination of bulbospinal inhibitory pathways; (2) strengthening of existing synapses, or formation of new synaptic connections from axonal sprouting in the spinal cord; (3) changes in synthesis, release, or actions of neurotransmitters, and (4) alterations in afferent input (afferent axonal sprouting) from peripheral organs. Recent reports of specific alterations in animal models are summarized by Morrison and colleagues (2005) as (1) increased sensitivity of C-fiber afferents, possibly involving NGF; (2) enlargement of dorsal root ganglion cells; (3) increased electrical excitability of afferents associated with a shift in expression of sodium channels from a high-threshold tetrodotoxin-resistant type to a low-threshold tetrodotoxin-sensitive type. Other findings possibly related to the development of LUT dysfunction after SCI have been reported as (1) increased concentrations of glutamate, glycine, and taurine (Smith et al, 2002); (2) disruption of bladder epithelium barrier function (Apodaca et al, 2003); (3) change from low affinity M₁ to high affinity M₃ receptors at prejunctional cholinergic nerve endings (Somogyi et al, 2003); (4) increased release of adenosine triphosphate (ATP) from bladder urothelium (Khera et al, 2004); (5) increased spinal cord NGF (Seki et al, 2004); and (6) alterations in smooth muscle myosin heavy chain gene expression (Wilson et al, 2005). Recently, in murine models of acute SCI, nicotinic or purinergic receptor mechanisms have been shown to be the primary mechanism for ATP release as atropine has been shown to be only partially effective in stimulating ATP release (predominantly a muscarinic receptor phenomenon in the absence of injury). These findings further indicate a change in receptor-mediated bladder activity associated with SCI (Salas et al, 2007). Yet another mechanism of bladder dysfunction may arise from modulation of TRPA-1 receptors, which has been shown to attenuate bladder overactivity in SCI models, indicating

Bladder dysfunction associated with acute SCI has been investigated in a variety of animal models. In rodent models using a moderate contusion injury at three different thoracic levels—T1, T4, or T9—versus complete crush injury at T1 and T9, differences in bladder function were noted. T4 and T9 contusions were associated with a relative increase in urinary retention, whereas T1 defects had less impact on retained volume. Lesions at T1 spared a critical descending modulating pathway for voiding in rats. Crush injuries were associated with much more defect emphasis (David and Steward, 2010). Receptor behavior has also been noted to change in SCI. Differential expression of channel receptors has been demonstrated in muscle strips from neurogenic patients. K_{ATP} calcium channels appear to regulate spontaneous hyperactivity in neurogenic patients as compared with normal individuals. However BK_{Ca} channels are more involved in regulation of normal patients as compared with neurogenic patients (Oger and AlKhawajah, 2010).

These topics are not further specifically considered in detail here, nor are the ramifications of this information relative to potential improvement of SCI after stem cell implant or reinnervation. Reviews can be found by Olson (1997); Fawcett (1998); Kakulas (1999); Rabchevsky and Smith (2001) (this also includes a discussion of pathophysiology and experimental models); Cao and coworkers (2002) (stem cell repair); Fawcett (2002) (repair of SCI); Rossi and Cattaneo (2002) (stem cell therapy); Mitsui and colleagues (2003) (stem cell repair); Kakulas (2004) (neuropathology and natural history of the spinal cord changes); and Livshits and associates (2004) (reinnervation).

Figure 75-1. Cystourethrogram in a 19-year-old woman with detrusor-striated sphincter dyssynergia secondary to a complete spinal cord injury at vertebral level T11. Image was taken during an involuntary bladder contraction with exaggerated bladder neck opening caused by the obstruction below. (From Nordling J, Olesen KP. Basic urographic and cystourethrogram patterns. In: Pollack HM, editor. *Clinical urography*. Philadelphia: Saunders; 1990. p. 1953.)

the importance of these receptors in the spinal cord-injured bladder (Andrade et al, 2011).

The characteristic pattern in a patient with a complete lesion above the sacral spinal cord is detrusor overactivity, smooth sphincter synergy (with lesions below the sympathetic outflow), and striated sphincter dyssynergia (Sullivan and Yalla, 1992; Thomas and O'Flynn, 1994; Chancellor and Blaivas, 1995a). Neurologic examination shows spasticity of skeletal muscle distal to the lesion, hyperreflexic DTRs, and abnormal plantar responses. There is impairment of superficial and deep sensation. Figures 75-1 to 75-3 typify the cystourethrogram and urodynamic patterns. The guarding reflex is absent or weak in most patients with a complete suprasacral SCI. In incomplete lesions the reflex is often preserved but quite variable (Morrison et al, 2005). The striated sphincter dyssynergia causes a functional obstruction with poor emptying and high detrusor pressure. In an effort to subclassify detrusor sphincter dyssynergia, Karsenty and colleagues (2005) retrospectively evaluated video-urodynamic recordings of patients with complete SCI with untreated neurogenic overactive bladder and detrusor sphincter dyssynergia. They identified two time periods within the tracings, with Delay A being defined as that period between the onset of external urethral sphincter (EUS) pressure increase and the subsequent onset of bladder pressure increase. Delay B was defined as the period between the onset of urethral sphincter pressure increase and the moment at which bladder pressure increase reached a level of 10 cm H₂O or greater above the baseline value. The recordings of 20 patients were assessed, with the Delay A timeframe found to be significant in 16 of 20 patients, with a meantime for delay of 2.2 seconds. There was a positive association between this delay and the completeness of the SCI and the presence of continuous DSD on electromyogram. Delay B was positive in all patients with a mean delay time of 7.6 seconds. The authors concluded that EUS contraction starts before the onset of bladder contraction in most patients with coexistent SCI and detrusor sphincter dyssynergia.

The presence of striated sphincter dyssynergia causes a functional obstruction with poor emptying and high detrusor pressures. Occasionally, incomplete bladder emptying may result from what seems to be a poorly sustained or absent detrusor contraction. This seems to occur more commonly in lesions close to the conus medullaris than with more cephalad lesions. This may result from a second occult lesion or may be caused by locally

Figure 75-2. Typical cystourethrogram configuration of a synergic smooth sphincter and a dyssynergic striated sphincter in a man during a bladder contraction. (From Nanninga JB. Radiological appearances following surgery for neuromuscular diseases affecting the urinary tract. In: Pollack HM, editor. *Clinical urography*. Philadelphia: Saunders; 1990. p. 2003.)

functioning reflex arcs, which result in detrusor inhibition from strong striated pelvic floor muscle contraction, or by a loss of higher center-mediated detrusor facilitation, which normally occurs after the initial increase in pressure during a bladder contraction (Thomas and O'Flynn, 1994). Once reflex voiding is established, it can be initiated or reinforced by the stimulation of certain dermatomes, such as by tapping the suprapubic area. The urodynamic and upper tract consequences of the striated sphincter dyssynergia vary with severity (usually worse in complete lesions), duration (continuous contraction during detrusor activity is worse than intermittent contraction), and anatomy (male is worse than female) (Linszenmeyer et al, 1998).

The type of dyssynergia also appears to be associated with degree of injury and potential for progression of dysfunction. Schurch and

colleagues evaluated 105 male patients with SCI and noted a correlation between type of DSD and completeness of spinal cord lesion. Men with incomplete sensory and motor lesions more commonly had type 1 DSD, whereas complete sensory and motor lesions were more commonly associated with either type 2 or type 3 DSD. There was no correlation, however, noted between the type of DSD and the lesion level. At long-term follow-up, DSD type was noted to evolve from type 2 or type 3 DSD in approximately a quarter of the studied patients, whereas 65% of patients remained stable with the same type of DSD at follow-up (Schurch et al, 2005).

KEY POINT: MANAGEMENT OF PATIENTS WITH SUPRASACRAL SPINAL CORD INJURY

- From a functional standpoint, the voiding dysfunction most commonly seen in suprasacral SCI represents both a filling or storage and an emptying or voiding failure. Although the urodynamics are “safe” enough in some individuals to allow only periodic stimulation of bladder reflex activity, many will require some form of additional treatment. If bladder pressures are suitably low or if they can be sufficiently and safely lowered with nonsurgical or surgical management, the problem can be treated primarily as an emptying failure. CIC can then be continued as a safe and effective way of satisfying many of the goals of treatment. The role of additive antimuscarinic administration appears to be supported by the preponderance of evidence in this patient population (Madersbacher et al, 2012). Recent consensus opinion has stressed the conservative use of antibiotics in patients using long-term CIC. Wyndaele and colleagues opined on the importance of demonstrating definitive evidence of UTI before initiating antimicrobial therapy in the population using this technique (Wyndaele, 2012). Alternatively, sphincterotomy, urethral stenting, or intrasphincteric injection of onabotulinumtoxinA can be used in males to lower the detrusor leak point to an acceptable level and render the patient incontinent, thus converting the dysfunction primarily to a storage failure (incontinence), which can be obviated either by timed stimulation or with an external collecting device. In the dexterous SCI patient, the former approach using CIC is becoming predominant. Electrical stimulation of the anterior sacral roots with some form of deafferentation is also now a distinct reality (Creasey et al, 2001; Seif et al, 2004). Although used sparingly, as with all patients with neurologic impairment, a careful initial evaluation and periodic, routine follow-up evaluation must be performed to identify and correct the following risk factors and potential complications: bladder overdistention, high-pressure storage, high detrusor leak point pressure, vesicoureteral reflux (VUR), stone formation (lower and upper tracts), and complicating infection, especially in association with reflux.

Sacral Spinal Cord Injury

After the patient has recovered from spinal shock, there is typically a depression of DTRs below the level of a complete lesion with varying degrees of flaccid paralysis. Sensation is usually absent below the lesion level. Detrusor areflexia with high or normal compliance is the common initial result. However, decreased compliance may also develop, a finding in some distal SCI lesions that most likely represents a complex response to neurologic decentralization probably involving reorganization and plasticity of neural pathways (Fam and Yalla, 1988; de Groat et al, 1997; Blaivas et al, 1998b). There is surprisingly little consensus on the evolution of the appearance or function of the bladder neck or smooth sphincter area after sacral SCI. The classic outlet findings are described as a competent but nonrelaxing smooth sphincter and a striated sphincter that retains some fixed tone but is not under voluntary control. Closure pressures are decreased in both areas

(Sullivan and Yalla, 1992; Thomas and O’Flynn, 1994). It is interesting to note that the late appearance of the bladder neck may be “open” (Kaplan et al, 1991). Attempted voiding by straining or Credé maneuver results in “obstruction” at the level of the potentially closed bladder neck or at the distal sphincter area if the sphincter tone is fixed (Fam and Yalla, 1988; Thomas and O’Flynn, 1994). Figure 75-4 illustrates the typical cystourographic and urodynamic pictures of the late phases of such a complete lesion.

Neurologic and Urodynamic Correlation

Although generally correct, the correlation between somatic neurologic findings and urodynamic findings in suprasacral and sacral SCI patients is not exact. A number of factors should be considered in this regard. First, whether a lesion is complete or incomplete is sometimes a matter of definition, and a complete lesion, somatically speaking, may not translate into a complete lesion anatomically and vice versa. In addition, multiple injuries may actually exist at different levels, even though what is seen somatically may reflect a single level of injury. Even considering these examples, all such discrepancies are not readily explained. In an assessment of 236 patients, with follow-up of mean 24 years, 43% of patients continue to report incontinence at time of follow-up with paraplegics reporting more frequently daily incontinence than tetraplegics (presumably because of catheter dependence of the latter group). Only 19% of patients used some form of medication for assistance in management of their incontinence. Surprisingly, CIC was associated with higher rates of incontinence than other types of bladder drainage techniques (Hansen et al, 2010). Further demonstration of the unpredictability of LUT status in patients with incomplete lesions was reported by Patki and colleagues (2006), who assessed a group of 43 men and 21 women with incomplete SCI (American Spinal Injury Association [ASIA] grades D and E) during a 2-year period. Forty patients initially assessed as having a bladder not at risk for deterioration ultimately experienced deterioration requiring CIC. Conversely, 5 of 20 patients who initially required CIC no longer required this with time. In long-term follow-up, 68% of patients continued to have abnormal urodynamic findings, and 37% of patients required a change in urologic management in the absence of perceptible change in neurologic status, indicating the potential for continued bladder changes in the absence of other detectable neurologic disease (Patki et al, 2005).

KEY POINT: MANAGEMENT OF PATIENTS WITH SACRAL CORD INJURY

- Potential risk factors and complications are those previously described, with particular emphasis on storage pressure, which can result in silent upper tract decompensation and deterioration in the absence of VUR. The treatment of such a patient is usually directed toward producing or maintaining low-pressure storage while circumventing emptying failure with CIC when possible. Pharmacologic and electrical stimulation may be useful in promoting emptying in certain circumstances (see Table 70-1 and Box 70-3 in Chapter 70).

In a classic article, Blaivas (1982) correlated clinical and urodynamic data from 550 patients with LUT dysfunction. In 155 patients with complete and incomplete suprasacral neurologic lesions, physiologically normal voiding was reported in 41%. DSD was demonstrated in 34%, and, surprisingly (and seemingly paradoxically), detrusor areflexia was noted in 25%. Other authors have noted detrusor areflexia with suprasacral SCI or disease, and the causes have been hypothesized to be a coexistent distal spinal cord lesion or a disordered integration of afferent activity at the sacral root or cord level (Light et al, 1985; Beric and Light, 1992). DSD was reported in 45% of 119 patients with suprasacral spinal cord lesions, whereas none of 36 patients with supraspinal neurologic

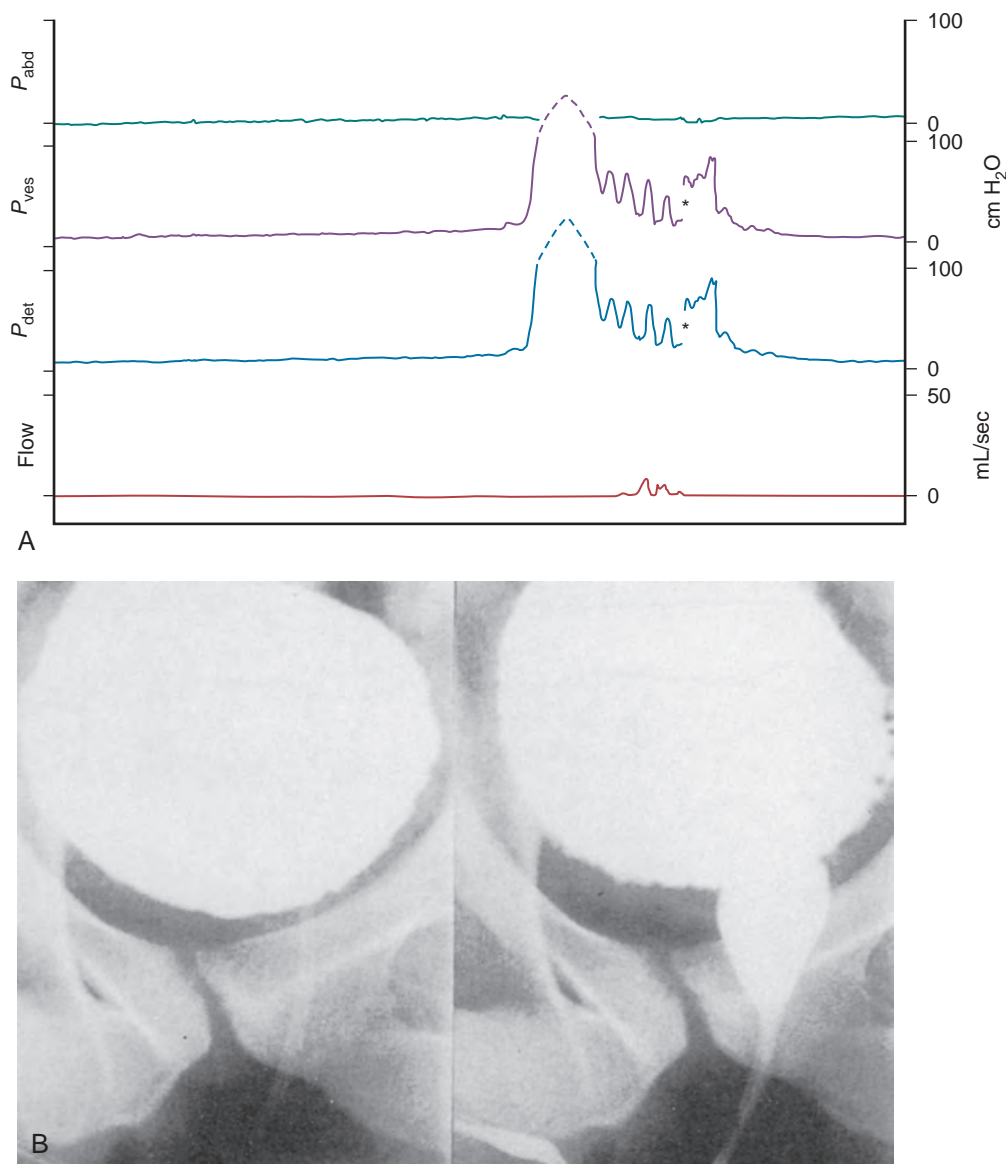

Figure 75-3. Video images in B at corresponding points of the urodynamic tracings in A. Detrusor hyperreflexia (P_{det} 150 cm H_2O), synergic bladder neck, dyssynergic striated sphincter. The asterisk represents a range change from a scale of 0 to 100 cm H_2O . (From Lawrence WT, Thomas DC. Urodynamic techniques in the neurologic patient. In: O'Reilly PH, George NJR, Weiss RM, editors. Diagnostic techniques in urology. Philadelphia: Saunders; 1990. p. 360.)

lesions had DSD. These data certainly support prior conclusions that (1) coordinated voiding is regulated by neurologic centers above the spinal cord and (2) a diagnosis of striated sphincter dyssynergia implies a neurologic lesion that interrupts the neural axis between the pontine-mesencephalic reticular formation and the sacral spinal cord. All 27 patients with neurologic lesions above the pons who were able to void did so synergistically (i.e., with relaxation of the striated sphincter followed by detrusor contraction). Twenty of these patients had detrusor overactivity, but 12 of the 20 had voluntary control of the striated sphincter, supporting a thesis of separate neural pathways governing voluntary control of the bladder and of the periurethral striated musculature. Most of these patients with detrusor overactivity secondary to suprapontine lesions were able to voluntarily contract the striated sphincter, but without abolishing bladder contraction. This seems to indicate that the inhibition of bladder contraction by pudendal motor activity is not merely a simple sacral reflex, but rather a complex neurologic event. Twenty-two of these patients had evidence of either sacral or infrasacral neurologic impairment of bladder function with

suprasacral control of striated sphincter function or vice versa. This provides a clinical correlate to the separate anatomic locations of the parasympathetic motor nucleus and the pudendal nucleus in the sacral spinal cord (see Chapter 69).

A subsequent study from the same center analyzed the results of urodynamic evaluation in 489 consecutive patients with either congenital or acquired SCI or spinal cord disease and correlated these with the diagnosed neurologic deficit (Kaplan et al, 1991). Although there was a general correlation between the neurologic level of injury and the expected vesicourethral function, the relationship was neither absolute nor specific. Twenty of 117 patients with cervical lesions exhibited detrusor areflexia, 42 of 156 with lumbar lesions had DSD, and 26 of 84 patients with sacral lesions had either detrusor overactivity or DSD. The patients were further classified on the basis of the integrity of the sacral dermatomes (intact sacral reflexes or not), which may explain some, but not all, of the apparent discrepancies. Of the patients with suprasacral cord lesions who had detrusor areflexia, 84% also had abnormal sacral cord signs (absent bulbocavernosus reflex, lax anal sphincter tone, or

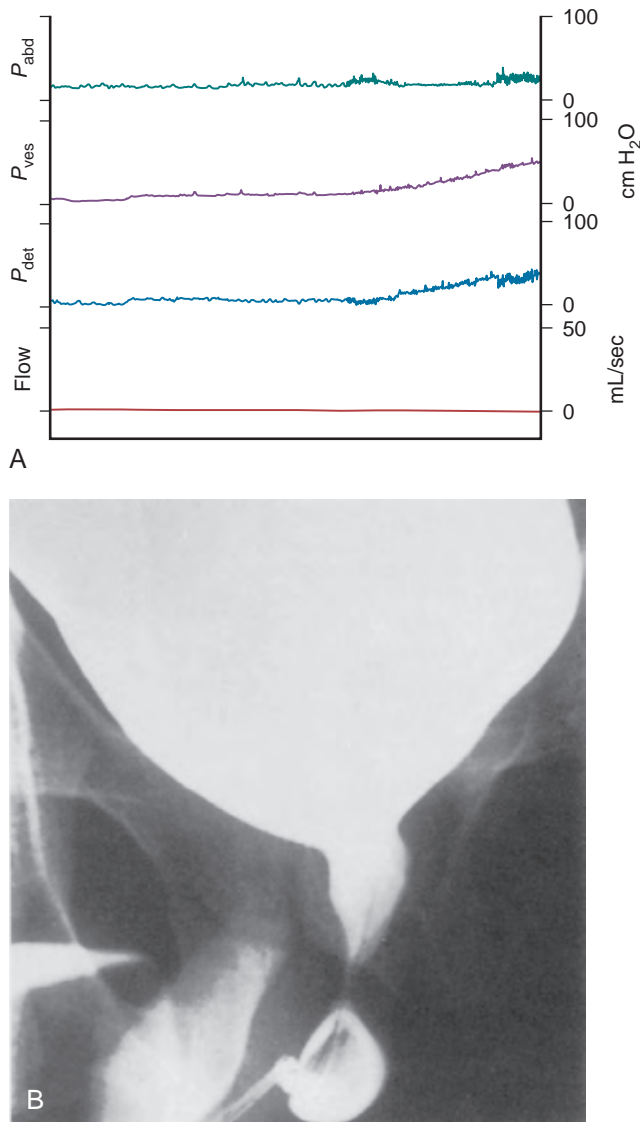

Figure 75-4. Simultaneous video (B) and urodynamic study (A) from a 28-year-old man whose bladder has been filled with 420 mL of contrast material. There is low compliance; the bladder neck is incompetent; and with straining the distal sphincter mechanism does not open—a pattern often seen in sacral spinal cord or efferent nerve root injury or disease. (From Lawrence WT, Thomas DC. *Urodynamic techniques in the neurologic patient*. In: O'Reilly PH, George NJR, Weiss RM, editors. *Diagnostic techniques in urology*. Philadelphia: Saunders; 1990. p. 362.)

sphincter electromyographic abnormalities indicative of lower motor neuron degeneration). All suprasacral cord lesion patients who had no evidence of sacral cord involvement had either detrusor overactivity or DSD.

Patients were also classified according to the three most common neurologic causes for their lesion: trauma, myelomeningocele, and spinal stenosis. Of the 284 trauma patients, all with thoracic cord lesions had either detrusor overactivity or DSD and absence of sacral cord signs. In contrast, patients with traumatic lesions affecting other parts of the spinal cord had a wide distribution of both urodynamic and sacral cord sign findings. For example, 38% of patients with traumatic lumbar cord injury had detrusor areflexia and positive sacral cord signs, 25% had DSD and negative sacral cord signs, 25% had detrusor overactivity and negative sacral cord signs, and 14% had either detrusor overactivity or DSD and negative sacral cord signs. Twenty of 25 patients with lumbar myelomeningocele had either detrusor areflexia or DSD, whereas all patients

with lumbar myelomeningocele and detrusor areflexia had positive sacral cord signs. Thirty-seven of 48 patients with sacral myelomeningocele had detrusor areflexia, and 35 had positive sacral cord signs. Of 54 patients with spinal stenosis, all those with cervical and thoracic cord lesions had either detrusor overactivity or DSD and negative sacral cord signs. Patients with a lumbar cord stenosis had no consistent pattern of detrusor activity or sacral cord signs. An open bladder neck at rest was found in 21 patients. All had either lumbar or sacral SCI. Sixteen of these had sacral cord lesions and detrusor areflexia. Decreased bladder compliance was noted in 54 patients, 41 of whom had sacral cord injury and 43 of whom had detrusor areflexia.

Wyndaele (1997) correlated the neurologic and urodynamic data in 92 patients with SCI and came to the same general conclusion: Although there was a general correlation between the neurologic level of injury and the expected vesicourethral function, it was neither absolute nor specific, especially in the group of patients with paraplegia resulting from spinal cord lesions at column level T10 to L2. With reference to this latter group, Pesce and coworkers (1997) reported on 46 patients with complete SCIs from vertebral lesions between T11 and L2. Fifty percent of the patients had detrusor areflexia and 50% had detrusor overactivity. Of the patients with detrusor overactivity, 16 also had DSD. Of 22 patients with lesions above vertebral level L1, 8 showed areflexia and 14 showed detrusor overactivity, of whom 9 demonstrated DSD. Of 9 patients with a lesion between T12 and L1, 3 showed detrusor areflexia and 6 overactivity, of whom 4 showed DSD. Of 15 patients with a lesion at L1 or lower, 3% showed detrusor overactivity and DSD.

Based on their review of 243 post-traumatic SCI patients who underwent complete spinal computed tomography (CT) or MRI, Weld and Dmochowski (2000) agreed that the correlation between somatic neurologic findings or spinal imaging studies and urodynamic findings in SCI patients is not exact. It should be noted that the authors' correlation between level of injury and urodynamic findings was better than those previously reported, most likely attributable to the precision of the radiologic imaging studies. Of 196 patients with suprasacral injuries, 94.9% demonstrated overactivity and/or DSD, 41.8% had low bladder compliance (defined as 12.5 mL/cm H₂O), and 40.3% had detrusor leak point pressures greater than 40 cm H₂O. Of the 14 patients with sacral injuries, 85.7% demonstrated detrusor areflexia; 78.6%, low compliance; and 85.7%, high leak point pressures. Of 33 patients with combined suprasacral and sacral injuries, 68% demonstrated detrusor overactivity and/or DSD, 27% had areflexia, 58% had low compliance, and 61% had high leak point pressures.

Other factors such as underlying histology may also contribute to upper tract deterioration. Ozkan performed full-thickness bladder biopsies in a group of patients undergoing augmentation cystoplasty for neurogenic detrusor overactivity. A relationship between the degree of and severity of detrusor fibrosis was noted to be a significant risk factor for upper tract deterioration. In addition, leak-point pressures of greater than 75 cm H₂O were also found to be consistent with upper tract deterioration (Ozkan et al, 2006).

In summary, all of these data suggest that management of the urinary tract in such patients must be based on urodynamic principles and findings rather than inferences from the neurologic history and evaluation. The presence of ambulation does not preclude significant urodynamic study abnormalities (Bellucci et al, 2012). Conversely, one should not make neurologic conclusions solely on the basis of urodynamic findings, although the information regarding "classic" complete lesions is for the most part valid (Cameron et al, 2012; Lenherr and Clemens, 2013).

Autonomic Hyperreflexia (Dysreflexia)

First described by Guttmann and Whitteridge in 1947, autonomic hyperreflexia (autonomic dysreflexia) is a potentially fatal emergency unique to the SCI patient. Excellent source materials include the reviews by Trop and Bennett (1991), Vaidyanathan and colleagues (1998), and Karlsson (1999). Autonomic hyperreflexia

represents an acute massive disordered autonomic (primarily sympathetic) response to specific stimuli in patients with SCI above the cord level of T6 to T8 (the sympathetic outflow). It is more common in cervical (60%) than thoracic (20%) spinal cord injuries. Onset after injury is variable—usually soon after spinal shock, but it may occur up to years after injury, and distal spinal cord viability is a prerequisite.

Symptomatically, autonomic hyperreflexia is a syndrome of exaggerated sympathetic activity in response to stimuli below the level of the lesion. The symptoms include pounding headache, hypertension, and flushing and sweating of the face and body above the level of the lesion. Bradycardia is a typical accompaniment, although tachycardia or arrhythmia may be present. Hypertension may vary in severity from causing a mild headache before voiding to life-threatening cerebral hemorrhage or seizure. The stimuli for this exaggerated response commonly arise from the bladder or rectum and typically involve distention. Precipitation may be the result of simple LUT instrumentation, tube change, catheter obstruction, or clot retention, and in such cases the symptoms resolve quickly if the stimulus is withdrawn. Additional causes or exacerbating factors may include other upper urinary tract or LUT pathology (e.g., calculi), gastrointestinal pathology, long bone fracture, sexual activity, electrocoagulation, and decubitus ulcers. In addition, with more SCI patients participating in athletic pursuits, the instigation of this condition related to sports activities is also being increasingly recognized (Krassioukov, 2012).

DSD invariably occurs, and, at least in males, smooth sphincter dyssynergia is also usually a part of the syndrome. The pathophysiology is that of nociceptive stimulation via afferent impulses that ascend through the cord and elicit reflex motor outflow, causing arteriolar, pilomotor, and pelvic visceral spasm and sweating. Normally, the reflexes would be inhibited by secondary output from the medulla, but because of the SCI this does not occur below the lesion level. Vaidyanathan and colleagues (1998) emphasized that the SCI disrupts control of the sympathetic preganglionic neurons because bulbospinal input has been lost, and the remaining regulation is accomplished by spinal circuits consisting of dorsal root afferent and spinal interneurons. Karlsson (1999), however, points out that the underlying pathogenic mechanisms may not be as simple as they first appear. The amplitude of the blood pressure reaction indicates involvement of a large vascular bed, perhaps larger than that of the skin and skeletal muscle. It may be that the splanchnic vascular bed is involved as well, either from the standpoint of active vasoconstriction or simply from a lack of the ability to exhibit compensatory vasodilatation. Afferent and efferent plasticity in the sympathetic nervous system may also be involved.

Urodynamics continues to be a critical component of the evaluation of the LUT in SCI. A study of 120 patients with suprasacral SCI undergoing urodynamics assessed the incidence of autonomic dysreflexia (defined as systolic blood pressure increase of 20 mm Hg or more); 42.6% of patients with injuries at T6 or above met criteria for the diagnosis of autonomic dysreflexia. Overall, 36.7% of patients experienced this condition. Surprisingly, 15.4% of patients with lesions below T6 experienced blood pressure elevations. Significant blood pressure increases were more commonly associated with DSD occurring continuously during bladder filling or in individuals with severely impaired bladder compliance as compared with individuals without those two variables. Most patients in this trial (75%) did not experience significant pulse rate changes (10 beats per minute), and, surprisingly, only 22.7% of those with the diagnosis of autonomic dysreflexia actually experienced bradycardia. The finding of dysreflexia in patients with lesions below the classically defined T6 level serves as a signal for close surveillance of SCI patients receiving LUT evaluation (Huang et al, 2011).

Ideally, any endoscopic procedure in susceptible patients should be done using spinal anesthesia or carefully monitored general anesthesia. Acutely, the hemodynamic effects of this

syndrome may be managed with β - and/or α -adrenergic blocking agents. Ganglionic blockers were once the mainstay of treatment (Wein, 2002a), but their usage has essentially been abandoned. Sublingual nifedipine is capable of alleviating this syndrome when given during cystoscopy (10 to 20 mg) and of preventing it when given orally 30 minutes before cystoscopy (10 mg) (Dykstra et al, 1987). The rationale for giving this medicine was that smooth muscle contraction would be prevented through its calcium antagonist properties, and the increase in peripheral vascular resistance normally seen with sympathetic stimulation would likewise be prevented. Before electroejaculation, Steinberger and colleagues (1990) recommended oral prophylaxis with 20 mg of nifedipine, finding this markedly lowered pressure rises during treatment. The use of sublingual nifedipine, however, has been prohibited in many medical centers.

Other rapidly acting agents have been reported to be beneficial, and labetalol is recommended by many anesthesiologists (Bycroft et al, 2005). Captopril, hydralazine, and diazoxide are still occasionally recommended but may be less advantageous (Furlan, 2013).

It is interesting to note that there seems to be no consensus on the acute pharmacologic management of autonomic dysreflexia when necessary. Krassioukov and colleagues (2009) extensively reviewed the level of evidence for various management strategies at the time and concluded that nifedipine, nitrates, and captopril were the most commonly used and recommended agents and were supported by level 2, 5, and 4 evidence, respectively.

Chancellor and colleagues (1994) reported on the use of terazosin (a selective α_1 -adrenergic blocker) for long-term management (3-month study) and prophylaxis of autonomic hyperreflexia. A nightly dose of 5 mg reduced severity, whereas erectile function and blood pressure were unchanged. Vaidyanathan and colleagues (1998) confirmed the success of prophylactic terazosin. They treated 18 tetraplegic adults and 3 paraplegics with gradually increasing doses of the drug, ultimately varying from 1 to 10 mg daily. The authors reported complete resolution of dysreflexic symptoms in all patients; only 1 tetraplegic patient required drug discontinuation because of persistent dizziness. Such prophylaxis may be particularly important in view of the fact that significant elevations in blood pressure can occur without other symptoms of autonomic hyperreflexia (Linsenmeyer et al, 1996).

Similar salubrious results have also been reported with prazosin as prophylaxis for this condition (Bycroft et al, 2005).

Prophylaxis, however, does not eliminate the need for careful monitoring during provocative procedures. There are patients with severe dysreflexia that is intractable to oral prophylaxis and correction by urologic procedures. For these unfortunate individuals, a number of neurologic ablative procedures have been used—sympathectomy, sacral neurectomy, sacral rhizotomy, cordectomy, and dorsal root ganglionectomy (Trop and Bennett, 1991). Hohenfellner and associates (2001) advocate sacral bladder denervation by sacral rhizotomy as a moderately invasive, relatively low risk procedure that, along with intermittent catheterization, produces good results in refractory patients.

Vesicoureteral Reflux

Surprisingly little is written about VUR in the SCI patient. The reported incidence varies between 17% and 25% of such patients (Thomas and Lucas, 1990), and the condition is more common in those with suprasacral SCI. Contributing factors include (1) elevated intravesical pressure during filling and emptying and (2) infection. Persistent reflux can lead to chronic renal damage and may be an important factor in the long-term survival of SCI patients. Hackler and coworkers (1965) reported that persistent reflux was present in 60% of SCI patients dying of renal disease. In patients with only transient VUR over a 5- to 15-year period, urography was normal or minimally changed in 83%. It should be noted that high storage and voiding pressures irrespective of VUR can be responsible for renal damage (McGuire, 1984; Vega and Pascual,

2001). Ku and associates reported on 179 men with SCI at a mean follow-up after injury of 29 years. The incidence of VUR in this group was 15.1%, whereas 34% of patients were diagnosed with pyelonephritis at some point during their follow-up. Nearly 25% developed renal stones, and 32% experienced upper tract deterioration as manifested by hydronephrosis. Upper tract degeneration was more prevalent in those managed with urethral catheters (51%) than in those managed with either spontaneous voiding or CIC. Urethral catheter drainage was inferior to all other forms of bladder drainage in terms of protecting the upper tracts, underscoring the inadvisability of chronic urethral catheterization in this patient population (Ku et al, 2005).

The best initial treatment for VUR in a patient with voiding dysfunction secondary to neurologic disease or injury is to normalize LUT urodynamics (i.e., decrease storage pressures and decrease outlet resistance) as much and as quickly as possible. Depending on the clinical circumstances, this may be achieved by pharmacotherapy, urethral dilatation (in the myelomeningocele patient), neuromodulation, deafferentation, augmentation cystoplasty, or sphincterotomy (Flood et al, 1994; Perkash et al, 1998). If this fails, the question of whether to operate on such patients for correction of the reflux or to correct the reflux while performing another procedure (e.g., augmentation cystoplasty) is not an easy one, because correction of reflux in a frequently very thickened bladder may not be an easy task.

Transureteroureterostomy for unilateral reflux is feasible, but even experienced urologists have had difficulties with ureteral calculi trapping, recurrent VUR, and obstruction at the vesicoureteral junction after such procedures in this difficult group of patients (Van Arsdalen et al, 1983). Submucosal trigonal injection of bulking substances has recently added a new dimension to the treatment of this difficult problem. Despite increased awareness of renal dysfunction related to high-pressure reflux in the SCI population, the prevalence of renal functional compromise in this population remains significant (Fischer et al, 2012).

Occasionally, bladder neck closure and permanent suprapubic drainage are indicated in the case of the severely dysfunctional or destroyed urethra arising from long-term indwelling catheterization (Colli and Lloyd, 2011). Urinary diversion continues to be a common method for management of LUT complications in this patient population (Peterson et al, 2012). However, in some cases, alternative diversion techniques using detubularized bowel segments may be successful (Khavari et al, 2012).

Finally, one must remember the potential artifact that significant reflux can introduce into urodynamic studies. Measured bladder capacity appears artifactually large, and measured pressures at given inflow volumes may appear lower than those after reflux correction. The apparent significance of detrusor overactivity may thus be underestimated.

Urinary Tract Infection

UTI is relatively common in patients with SCI. UTI or bacteriuria may occur in up to 57% of patients with SCI in the first year after initial hospitalization (Morton et al, 2002). Recurrent infections may be a manifestation of upper or lower tract calculi, symptomatic or silent pyelonephritis, or LUT dysfunction causing persistently elevated residual urine. In conjunction with poor urodynamic function, UTI can lead to high morbidity, poor quality of life, and decreased life expectancy in patients with SCI (Sauerwein, 2002). The use of antibiotics in SCI patients remains a topic of controversy. A consensus reached by the National Institute on Disability and Rehabilitation Research Group in 1992 stated that bacteriuria should be treated only when the patient has signs or symptoms of a UTI (Penders et al, 2003). In a comprehensive review, Biering-Sorensen and coworkers (2001) recommended the following: (1) Treat bacteriuria only if symptomatic; (2) use antimicrobial agents, if possible, with little or no impact on normal flora; (3) treat at least 5 days, and 7 to 14 days for those with reinfection or relapse; (4) repair structural and functional risk factors; (5) use prophylaxis

only in those with recurrent UTI when no underlying cause can be found and especially in those patients with dilated upper tracts; and (6) do not use antibiotics to prevent UTI in patients with an indwelling catheter. They regard the use of prophylactic antibiotics in patients on CIC as controversial.

Morton and coworkers (2002) concluded from a meta-analysis of 15 controlled trials that prophylactic antibiotics were not generally helpful, but added that they could not exclude a clinically important effect, especially in those who had recurrent UTI that limited their functioning and well-being. Sauerwein (2002) recommended beginning antibiotic prophylaxis in patients on CIC and stopping after 1 year if there has been one UTI or fewer. Some (Burns et al, 2001) believe that significant pyuria, defined as 8 to 10 or more white blood cells per high-power field, denotes tissue invasion and is an indication for antibiotic treatment. At the end of the day, there are few evidence-based data in this area (Hooton et al, 2010). In addition, the role of catheter type and infection risk has extensively been assessed, with evidence supporting the use of hydrophilic catheters (Bermingham et al, 2013; Li et al, 2013).

Spinal Cord Injury in Women

There are many aspects of management of the LUT affected by SCI that are specific to women (Yang and Cardenas, 2001). The incidence of SCI is highest among young men and older women (McColl, 2002). The body composition of women with SCI shows deficient protein and bone mass and excess fat, predisposing them to an increased risk of skin breakdown and incidence of fractures, a finding compounded by osteoporosis. The symptoms of menopause (e.g., hot flashes) may be difficult to distinguish from those of autonomic dysreflexia, and incontinence and UTIs worsen with age in women in the general population and particularly in those with SCI (Kalpakjian et al, 2010).

Suitable bladder reservoir function can usually be achieved either pharmacologically or surgically, and paraplegic women can usually master CIC; however, special difficulty is encountered in these patients owing to the lack of an appropriate external collecting device. Although some tetraplegic women can be trained to perform CIC, there is no practical alternative to indwelling catheterization for most (Lindan et al, 1987). Although there are reports of long-term drainage with an indwelling urethral catheter being well tolerated in the long term, McGuire and Savastano (1986) point out that this may often not be the case because of significant incontinence around the catheter and the development of upper tract changes (Kalpakjian et al, 2010).

For those spinal cord-injured female patients who can perform CIC or who have around-the-clock medical or family care, creation of adequate bladder reservoir function is reasonable. For those not in this category, the alternatives are limited and challenging. Bennett and associates (1995) compared the incidence of major complications in a group of female SCI patients who were managed long term by (1) CIC; (2) reflex voiding and incontinence padding; and (3) an indwelling catheter. There were 10 major complications in the 25 patients in group 2, 58 in the 22 patients in group 3, and only four major complications in group 1. Singh and Thomas (1997) looked at the results of treatment in a group of female tetraplegics. Twenty-three of 27 patients with complete lesions wound up using an indwelling catheter, 3 underwent diversion, and in 1 patient the caregiver performed CIC. In 20 patients with incomplete lesions, all with poor functional recovery, 14 had permanent indwelling catheters, 3 were able to perform CIC, and 3 used reflex voiding by triggering. Of 37 patients with incomplete lesions with good functional recovery, only 3 required indwelling catheterization, 4 used CIC, and most were able to use reflex voiding by triggering. The authors noted also that 55% of the women with permanent catheters had bladder calculi, 35% had leakage around the catheter, and 33% had recurrent symptomatic infection. Although upper tract changes were seen in only 5%, it is obvious that the authors consider that, for the most part, female patients

with voiding dysfunction secondary to cervical SCI who exhibit poor functional recovery represent urologic failures of management. Surgical intervention for stress urinary incontinence in this population also may be beneficial in well-selected patients. Mid-urethral tapes have been reported to produce reasonable outcomes in selected women with SCI (Pannek, 2012). Other groups have reported durable and safe results using autologous tissue as the sling type (Athanasopoulos et al, 2012).

Spinal Cord Injury (Neurogenic Bladder) and Bladder Cancer

There is a strong association between the development of bladder cancer and long-term indwelling catheterization. Kaufman and colleagues (1977) initially reported squamous cell carcinoma of the bladder in 6 of 59 patients with SCI who had long-term indwelling catheters. Four of these patients had no obvious tumors visible at endoscopy, and the diagnosis was made by bladder biopsy. Five of these patients also had transitional cell elements in their tumor. Broecker and associates (1981) surveyed 81 consecutive SCI patients with an indwelling urinary catheter for more than 10 years, and, although the investigators did not find frank carcinoma in any patient, they found squamous metaplasia of the bladder in 11 and leukoplakia in 1. Locke and coworkers (1985) noted 2 cases of squamous cell carcinoma of the bladder in 25 consecutive SCI patients catheterized for a minimum of 10 years. Bickel and colleagues (1991) reported 8 cases of bladder cancer in men with SCI, although the denominator was uncertain. Four of the men had been managed by indwelling catheterization for 7, 10, 14, and 19 years, respectively. All of these 4 had transitional cell carcinoma, whereas in the other 4 men there were 2 cases of transitional and 2 of squamous cell carcinoma. In Chao and colleagues' series (1993), 6 patients developed bladder cancer, 3 of whom had indwelling catheters (of a total of 32) and 3 of whom (of 41) did not. Stonehill and associates (1996) retrospectively reviewed all bladder tumors in their SCI patients for 7 years and compared these with matched controls. They found 17 malignant and 2 benign bladder tumors, with indwelling catheters and a history of bladder calculi being statistically significant risk factors.

Hess and associates (2003) reported their own series and summarized one view of the literature regarding SCI and bladder cancer: (1) The relative risk in SCI patients is 16% to 28% greater than the general population; (2) the overall incidence is 2.3% to 10%; (3) there is a higher proportion of squamous cell than transitional cell carcinoma; (4) the prevalence peaks at an earlier age than in the general population; (5) diagnosis is often made at a more advanced stage; (6) risk factors include chronic indwelling catheterization, bladder stones, and chronic UTI; (7) neither cystoscopy nor cytology is an entirely reliable diagnostic tool; and (8) those with multiple risk factors should have a more aggressive evaluation.

Tempering these views are reports by Pannek (2002), who reviewed the data from 43,561 SCI patients in three countries and concluded that the incidence of bladder cancer is comparable to that of the general population; however, more than 60% of those affected had muscle invasive disease on initial presentation. Chronic indwelling catheters and persistent or recurrent UTI are suggested as risk factors rather than the SCI itself. Subramonian and associates (2004), in an assessment of spina bifida patients, reported similar conclusions regarding age-standardized incidence of bladder cancer relative to the general population. They reported a lifetime risk of 2.4% in their reported population. This compares with a lifetime risk estimation of 30.7 to 720 per 100,000. Seventy-five percent of the affected patients in the series had indwelling catheters for 18 to 32 years.

The incidence of bladder cancer in MS patients with indwelling catheters is estimated to be 0.29%, as compared with 0.004% in the general population of females and 0.018% in the population of males. The incidence of bladder cancer in SCI patients has been recorded to range from 0.27% to 9.6%; however, in larger series the overall incidence is 0.27% to 0.37%. The natural history of bladder cancer is thought to be more highly aggressive in neurogenic

patients and is responsible for 0.3% to 2.8% of known deaths in the SCI population.

Follow-Up

Linszenmeyer and Culkin (1999) reported the American Paraplegia Society (APS) guidelines for urologic care of SCI. Annual follow-up is recommended for the first 5 to 10 years after injury, and if the patient is doing well, then follow-up every other year is advised. Upper and lower tract evaluation should be done initially, yearly for 5 to 10 years, and then every other year. Burns and associates (2001) recommended at least plain films and nuclear renal scans, with a decrease of more than 20% in renal plasma flow warranting further investigation. Urodynamic evaluation was recommended by the APS at the same intervals as upper and lower tract screening. Cystoscopy was recommended annually in those with an indwelling catheter.

In 2006, the Consortium for Spinal Cord Medicine detailed a set of guidelines for bladder management in adults with SCI and stated only that, in general, a urologic evaluation should be done yearly, although no studies exist on the optimum frequency of such examinations or the tests that should be included (Consortium for Spinal Cord Medicine, 2006).

The European Association of Urology (EAU) guidelines for follow-up of all neurogenic LUT dysfunctions call for meticulous and regular re-evaluations at intervals of no more than 1 to 2 years, and more frequently for patients with MS and acute SCI and other unstable conditions. They include the following guidelines: (1) Supply the patient with urinary dipsticks to check the urine at least every 2 months and whenever a urinary infection is suspected; (2) perform upper urinary tract and bladder morphology every 6 months (ultrasonography), along with residual urine determination; (3) conduct physical examinations and blood chemistries yearly; (4) obtain detailed specialist investigation every 1 to 2 years and on demand when risk factors emerge (Pannek et al, 2011).

Cervical Myelopathy

Cervical myelopathy is usually caused by compression, secondary to spondylosis, ossification of the posterior longitudinal ligament, or cervical disk herniation (Sakakibara et al, 1995a; Mochida et al, 1996). Sakakibara and associates (1995a) studied 128 affected patients, of whom 95 had voiding symptoms, 61 had storage symptoms, 71 had obstructive symptoms, and 25 had urinary incontinence. Urodynamic studies revealed detrusor overactivity in 61 patients and DSD in 22. On the other hand, Mochida and colleagues (1996) reported that 22 of 60 (37%) patients undergoing surgery for cervical myelopathy were found to have neuropathic bladder dysfunction on urodynamic evaluation. Of these, 9 (41%) were found to have detrusor overactivity, but 13 (59%) were characterized as having an underactive detrusor. Because these findings are at odds with what one would expect with only cervical spinal cord pathology, the need for urodynamic study to optimally guide therapy in patients with neurogenic bladder is reinforced.

Acute Transverse Myelitis

Acute transverse myelitis is a rapidly developing condition with motor, sensory, and sphincter abnormalities, usually with a well-defined upper sensory limit and no signs of spinal cord compression or other neurologic disease (Kalita et al, 2002). It may result from a variety of mechanisms—parainfectious, autoimmune, vascular, or demyelinating (Ganesan and Borzyskowski, 2001). The condition usually stabilizes within 2 to 4 weeks and is not progressive afterward; however, recovery may be variable and some residual neurologic deficits are possible. Although recovery is more variable, and the prognosis, in general, is more favorable, the development and nature of voiding dysfunction have been reported to be similar, level by level, to those of SCI (Sakakibara et al, 1995b). Kalita and colleagues (2002) reported on 18 patients with acute transverse

myelitis whose 6-month outcome included persistent retention in 6 and storage symptoms in 10, of whom 5 had emptying problems as well. Only 2 patients had regained normal voiding. In the acute state, urodynamics showed an areflexic or contractile bladder in 10, detrusor overactivity with poor compliance in 2, and DSD in 3. Seventeen had had urinary retention on presentation. As in SCI, urodynamic studies are necessary to guide irreversible therapy because the activity of the bladder and outlet during storage and emptying does not always correspond to the expected pattern based on the level of pathology.

Neurospinal Dysraphism

Neurospinal dysraphism is covered primarily in Chapter 142; however, certain considerations regarding the adult with these abnormalities should be mentioned. *Spinal dysraphism* refers to the malformation of the vertebral arches and, commonly, malformation of the neural tube. The term includes spina bifida occulta, which involves only a bony (vertebral) arch defect; and spina bifida cystica (aperta), which involves a bony defect and a neural tube (spinal cord) defect. The two primary subclasses of spina bifida cystica are myelomeningocele (the nerve roots or portions of the spinal cord have evaginated beyond the vertebral bodies) and meningoceles (which contain only a herniated meningeal sac with no neural elements). If fatty tissue is present in the sac in either case, the prefix *lipo-* is added (Churchill et al, 2001). Myelomeningocele accounts for more than 90% of spina bifida cystica and is the most devastating condition in terms of sequelae. Of myelomeningoceles, 2% are cervical, 5% thoracic, 26% lumbar, 47% lumbosacral, and 20% sacral. The level(s) of the lesion correlate(s) poorly with urodynamic findings (Churchill et al, 2001). Myelomeningocele occurs in approximately 1 per 1000 live births (Wyndaele et al, 2005; Drake et al, 2013). The incidence of LUT dysfunction is not absolutely documented, but most studies suggest an incidence of over 90% (Wyndaele et al, 2005; Drake et al, 2013). The incidence of spina bifida has decreased in recent years owing to the recognition of the importance of folate ingestion in pregnant women and also advanced prenatal diagnostic capabilities resulting in selective termination of pregnancies. However, up to 85% of patients with spina bifida do survive to adulthood, and therefore this condition is becoming a more significant chronic care issue in the general population. Transitional care from childhood through adolescence to adulthood now is becoming a focus of specialized clinics despite the fact that many barriers do exist (Summers et al, 2014).

McGuire and Denil (1991) and Woodhouse (2005) point out that, owing to progress in the overall care of children with myelodysplasia, urologic dysfunction often becomes a problem of the adolescent or adult with this disease. In McGuire and Denil's (1991) experience, the "typical" myelodysplastic patient shows an areflexic bladder with an open bladder neck. The bladder usually fills until the resting residual fixed external sphincter pressure is reached, and then leakage occurs. Stress incontinence may also occur owing to changes in intra-abdominal pressure. A small percentage (10% to 15%) of patients demonstrate DSD, but these individuals show normal bladder neck function that, if detrusor reflex activity is controlled, may be associated with urinary continence. After puberty, most authors report that the majority of myelodysplastic patients note an improvement in continence, but at that age and afterward they are less inclined than children to tolerate any degree of incontinence. In adult patients the problems encountered in myelodysplastic children still exist but are often compounded by prior surgery, upper tract dysfunction, and one form of urinary diversion or another.

Perhaps the most important intervention for myelomeningocele is amelioration of the initial impact of the disease. A recent prenatal intervention trial was discontinued before study completion when the primary outcome of fetal or neonatal death or the need for cerebrospinal fluid shunt by age of 12 months was substantially less in the treated group. An additional primary outcome of overall mental development and motor function at age 30 months

showed that in individuals undergoing prenatal surgery, substantial improvement was encountered as compared with those receiving only postnatal interventions. In the prenatal surgery group, 40% of patients required cerebrospinal fluid shunts, whereas 82% of those in the postnatal group did. In addition, highly significant improvement in motor function and mental development was noted in the prenatal as compared with the postnatal group. A variety of secondary outcomes also were improved in this group, including the risk of hindbrain herniation at 12 months and ambulation by 30 months. However, there was an increased risk of preterm delivery and uterine dehiscence at delivery in the prenatal group as compared with the postnatal group. Nonetheless, this randomized trial of prenatal versus postnatal repair showed significant benefits to prenatal repair, resulting in termination of this trial on elevation of this intervention to a primary consideration for the condition of prenatally diagnosed myelomeningocele (Adzick et al, 2011).

The treatment strategy in women is to increase urethral sphincter efficiency without causing an increase in urethral closing pressure significant enough to result in a change in bladder compliance (McGuire and Denil, 1991). Periurethral injection therapy may be a safer option than the pubovaginal sling and artificial urethral sphincter in this case. The authors also believe that stress incontinence in men with myelodysplasia may follow similar general rules as in women, and bulking agents may give good results in this group as well. When the urethra is very widely dilated and somewhat rigid, and neither procedure alone will provide sufficient coaptation, it may be possible to combine a "prostatic sling" with periurethral bulking. Continent individuals will remain on CIC.

Nowhere is the failure of a neurologic examination to predict urodynamic behavior more obvious than in patients with myelomeningocele. Van Gool and colleagues (2001) categorized the urodynamic findings in 188 children with myelomeningocele into five groups: (1) normal detrusor and sphincter activity (7%); (2) detrusor overactivity and an inactive sphincter (11%); (3) detrusor overactivity and an overactive sphincter (45%); (4) inactive detrusor and inactive sphincter (23%); and (5) an inactive detrusor and an overactive sphincter (14%). In 16 adults with myelomeningocele, Sakakibara and associates (2003a) reported detrusor overactivity in 38%, low compliance in 81%, impaired bladder sensation in 25%, DSD in 50%, low maximum urethral pressure in 56%, and silent sphincter electromyographic findings in 25%. Webster and colleagues (1986) reported that 62% of their patients with myelomeningocele had detrusor overactivity, whereas 38% had detrusor areflexia. Thirty of 34 patients in the latter group had low compliance with high terminal filling pressures. Striated sphincter behavior was characterized as follows: true DSD in 15%, an apparently innervated but fixed nonrelaxing sphincter in 15%, and some evidence of striated sphincter denervation in 69%. Regardless of the pattern of LUT dysfunction in the adult, the main goal of therapy is the avoidance of high storage pressures (McGuire and Denil, 1991; Persun et al, 1999; Woodhouse, 2005).

LUT dysfunction secondary to occult spinal dysraphism may not manifest in childhood, and such patients may be referred as adults for symptoms as commonplace as urinary incontinence or recurrent UTIs. Delayed diagnosis of such voiding dysfunction has been reported by several authors (Jakobsen et al, 1985; Yip et al, 1985) and the specific dysfunction is dependent on the level and extent of the neurologic injury.

The urologic rehabilitation of patients with spinal dysraphism relies primarily on medical management and intravesical injection of onabotulinumtoxinA, with the selective use of augmentation enterocystoplasty or urinary diversion if failure occurs. However, surgery does not necessarily yield superior results. In a review of 421 patients managed for complications relating to spina bifida, 45% were treated medically, either with CIC, spontaneous voiding, or no specific method, and 55% were treated surgically. Overall incontinence episodes were higher in the surgical management group; however, these outcomes may have been reflective of the aggressiveness of management as well as the severity of disease (Lemelle et al, 2006). A recent evaluation of individuals being

followed long term for myelomeningocele (20-year follow-up) found that 7 patients (13% of the original 52 followed) had unilateral renal dysfunction and 8 (15%) had bilateral overall renal dysfunction. Those with bilateral dysfunction had a significantly higher risk of detrusor overactivity during childhood urodynamic evaluation (63%) compared with those with normal function (24%). Overall, 48% of patients were continent at follow-up. Eight patients required surgical intervention sometime during the course of their condition. Nine used regular antimuscarinic ingestion, and 3 had had intravesical botulinum toxin injection. In addition, 27 required intermittent catheterization for management. Therefore urodynamic findings may be predictive of long-term consequences (Thorup et al, 2011). Surgery remains a salvage option for those not optimally managed by medical intervention. A recent assessment of national data practices using administrative data sets from a nationwide inpatient sample assessed patients undergoing bladder augmentation versus ileal conduit urinary diversion over a 7-year timeframe (1998 to 2005) for the primary diagnosis of spina bifida. Overall, 3403 patients underwent bladder augmentation, whereas 772 underwent ileal loop diversion. The bladder augmentation group tended to be younger patients (16 vs. 36 years) and more commonly male (52%). Urinary diversion was more commonly associated with the female patients as well as older patients. Overall, those undergoing urinary diversion had higher health care expenses and longer hospital stays. There was some difference in care choice based on insurance status (Wiener et al, 2011).

Recently, neural rerouting has been proposed as a potential option for some of these individuals. Ziao and colleagues have performed microanastomosis of the fifth lumbar ventral root to the third sacral ventral root to bypass low-level spina bifida injury. Initial improvements in bladder compliance and urinary incontinence were noted in patients and paralleled similar findings in patients with SCI (Joseph, 2005).

Tethered cord syndrome (TCS) is defined as a stretch-induced functional disorder of the spinal cord with its caudal part anchored by inelastic structures and restricting vertical movement. The anchoring structures can include scar from prior surgery, fibrous or fibroadipose filum terminale, a bony septum, or tumor (Yamada et al, 2004a, 2004b). Adults with TCS can be divided into those with a prior history of spinal dysraphism with a previously stable neurologic status who present with subtle progression in adulthood and those without associated spinal dysraphism who present with new-onset subtle neurologic symptoms (Yamada et al, 2004a, 2004b). Symptoms can include back pain, leg weakness, foot deformity, scoliosis, sensory loss, and bowel or LUT dysfunction (Phuong et al, 2002). TCS is reported to occur in 3% to 15% of patients with myelomeningocele. There is no typical dysfunction in TCS, and treatment must be based on urodynamic evaluation. LUT dysfunction may not be present until the teenage years or later (Kaplan and Blaivas, 1988; Husmann, 1995). Giddens and colleagues (1999) point out that, whereas children often develop symptoms of tethered cord after growth spurts, in adults the presenting symptomatology often follows activities that stretch the spine, such as sports or motor vehicle accidents. In adults, urologic presentation can include storage or voiding symptoms, incontinence, or complete retention. In a group of adult patients, urgency (67%) and urgency incontinence (50%) were the most common findings at presentation. Pretreatment urodynamics in 18 patients revealed detrusor overactivity in 72%, DSD in 22%, decreased sensation in 22%, decreased compliance in 17%, and what was termed a "hypocontractile" detrusor in 11%. It is interesting that postoperative urodynamic findings improved in only 29% and were unchanged in 71%. Steinbok and associates (2007) assessed eight children undergoing section of the filum that induced the tethered cord and compared them with seven children who had abnormal urodynamic findings and did not undergo filum release. Clinical improvement occurred in seven of the eight children at a mean follow-up of 3 years with improved urodynamics in four of seven children tested after surgery. These improvements were also associated with nonurologic functional

improvements (i.e., motor leg function). Two patients in the non-surgical group had urologic improvement at a mean follow-up of 3 years; however, three patients required surgical intervention and five had persistence of nonurologic symptoms. Thus, section of the cord appeared to improve function as compared with conservative, nonsurgical management.

Not all symptoms of tethered cord are remediated by surgery. In a retrospective assessment of 29 patients undergoing first-time tethered cord release, clinical symptoms were evaluated at 1 and 3 months after surgery as well as every 6 months thereafter. Garces-Ambrossi and coworkers (2009) addressed rates of improvement in motor and urinary dysfunction over time. The most common causes of tethered cord included lipomyelomeningocele (10%), tight filum (10%), lumbosacral lipoma (14%), intradural tumor (10%), and previous surgery in 7%. In addition, 48% of patients had had previous repair of myelomeningocele defects. Symptoms before intervention occurred for a mean of 5 months. Symptomatic presentation included diffuse pain and paresthesias in both lower extremities (45%) or perineum (62%). Lower extremity weakness was noted in patients with gait disturbances (59%) and bladder dysfunction (48%). Multilevel laminectomy accompanied by duraplasty (30% of patients) was performed as the primary intervention. At 18 months postoperatively, 47% of the patients with urinary symptoms had improvement in those symptoms, 69% had improvement in the lower extremity weakness, and 79% had improved painful dysesthesias. Mean time for improvement was 1 month for pain and 2.3 months for motor symptoms. Urinary symptoms lagged at 4.3 months. The majority of patients demonstrated improvement within 6 months of surgery (96%). After 1 year, only 4% showed no improvement (Garces-Ambrossi et al, 2009).

Recent emphasis on transitional aspects of care from childhood to adulthood has centered on the need for meticulous follow-up and optimization of bladder and renal function in light of social stigma, patient concerns, independence, and also bowel-related dysfunction. Consensus agreement stresses the need for established algorithmic approaches for follow-up inclusive of annual surveillance for early identification of urinary tract deterioration. These assessments should include renal and bladder ultrasonography and urodynamics when indicated (by symptomatic change or clinical physical examination finding). In addition, serum creatinine and renal scintigraphy may be performed when upper tract changes are suspected. Goals of therapy include reduction in detrusor pressure and maintenance of bladder compliance and social continence (de Kort et al, 2012).

Tabes Dorsalis, Pernicious Anemia

Although syphilitic myelopathy is rapidly disappearing as a major neurologic problem, involvement of the spinal cord dorsal columns and posterior sacral roots can result in a loss of bladder sensation and large postvoid residual urine volumes and therefore can be a cause of "sensory neurogenic bladder" (see Chapter 70). Although this represents the classic tabetic bladder (Wheeler et al, 1986), Hattori and coworkers (1990) reported on some patients with only tabes as an obvious cause of their LUT dysfunction who had low compliance or detrusor overactivity. Another spinal cord cause of the classic "sensory bladder" is the now uncommon pernicious anemia that produced this disorder by virtue of subacute combined degeneration (SACD) of the dorsolateral columns of the spinal cord. Pernicious anemia is a disease caused by impaired uptake of vitamin B₁₂ resulting from the lack of intrinsic factor in the gastric mucosa.

Poliomyelitis

Although not always present, when voiding dysfunction is seen in patients with polio it is that of a typical "motor neurogenic bladder" (see Chapter 70), with urinary retention, detrusor areflexia, and intact sensation. The reported incidence of LUT dysfunction in patients with polio was described as ranging from 4% to 42% by Bors and Comarr (1971).

DISEASE DISTAL TO THE SPINAL CORD

Disk Disease

Goldman and Appell (2000a, 2000b) nicely summarize the anatomic and neurologic considerations applicable to voiding dysfunction from lumbar disk disease. In the adult, the sacral segments of the spinal cord are at the level of the L1 and L2 vertebral bodies. In this distal end of the spinal cord (conus medullaris), the spinal cord segments are named for the vertebral body at which the nerve roots exit the spinal canal. Thus, although the sacral spinal cord segment is located at vertebral segment L1, its nerve roots run in the subarachnoid space posterior to the L2 to L5 vertebral bodies until reaching the S1 vertebral body, at which point they exit the canal. Therefore all of the sacral nerves that originate at the L1 and L2 spinal column levels run posterior to the lumbar vertebral bodies until they reach their appropriate site of exit from the spinal canal. This group of nerve roots running at the distal end of the spinal cord is commonly referred to as the *cauda equina*.

Usually, disk prolapse is in a posterolateral direction, which does not affect the majority of the cauda equina. However, in 1% to 15% of the cases (Goldman and Appell, 2000b), central disk prolapse occurs and compression of the cauda equina may result. Thus, disk prolapse anywhere in the lumbar spine could interfere with the parasympathetic and somatic innervation of the LUT, striated sphincter, and other pelvic floor musculature, and afferent activity from the bladder and affected somatic segments to the spinal cord. Most disk protrusions compress the spinal roots in the L4 to L5 or L5 to S1 vertebral interspaces. When LUT dysfunction is present, it typically occurs with the usual clinical manifestations of low back pain radiating in a girdle-like fashion along the involved spinal root areas. The most characteristic findings on physical examination are sensory loss in the perineum or perianal area (S2 to S4 dermatomes), sensory loss on the lateral foot (S1 to S2 dermatomes), or both.

In a review of the literature on LUT dysfunction associated with lumbar disk disease, Goldman and Appell (2000b) found that the incidence ranged from 27% to 92%, although the true incidence is unknown because many series describe findings only in patients with LUT dysfunction. Bartolin and colleagues (1998) found detrusor areflexia in 27% and normal detrusor activity in the remaining 73% of 114 patients with lumbar disk protrusion. All 31 patients with detrusor areflexia reported difficulty voiding with straining, and patients with voiding dysfunction generally presented with these symptoms or in urinary retention. The most consistent urodynamic finding was that of a normally compliant areflexic bladder associated with normal innervation or findings of incomplete denervation of the perineal floor musculature. In a later report, Bartolin and colleagues (2002) describe findings in 122 patients with lumbar disk protrusion. Detrusor areflexia was found in 32 (26%) and normal bladder urodynamic findings in 90 (74%). All with areflexia complained of difficulty voiding; 8 could not void at all, 14 had an interrupted flow, and 10 had a continuous but low flow. Occasionally, patients may show detrusor overactivity, attributed to irritation of the nerve roots (O'Flynn et al, 1992).

The detrusor areflexia associated with lumbar disk protrusion shows a lower incidence of concomitant decreased compliance than in the voiding dysfunction associated with myelomeningocele. Sandri and coworkers (1987) offered two possible explanations for this difference: (1) The effect of the disk represents a more incomplete lesion of the preganglionic parasympathetic fibers, and (2) the lesion is more sensory than motor, implying that the decreased compliance seen with the type of neural lesion in myelomeningocele is primarily caused by injury of the preganglionic parasympathetic motor fibers to the bladder.

Laminectomy may not improve LUT function in many cases, and prelamination urodynamic evaluation is prudent because it may be difficult postoperatively to separate causation of voiding dysfunction resulting from the disk sequelae from changes secondary to the surgery. In a group of patients with lumbar disk protrusion who underwent corrective surgery, Bartolin

and colleagues (1999) reported that detrusor activity returned to normal in only 6 of 27 patients with preoperative detrusor areflexia. Of the 71 patients with normal urodynamic findings preoperatively, 4 developed detrusor overactivity and 3 developed postoperative detrusor areflexia. The medicolegal implications of a presurgical and postsurgical urodynamic evaluation are obvious.

Cauda equina syndrome is a term applied to the clinical picture of perineal sensory loss with loss of voluntary control of both anal and urethral sphincter and of sexual responsiveness. This can occur not only secondary to disk disease (severe central posterior disk protrusion) but also to other pathologic processes affecting the spinal canal. Yamanishi and associates (2003) place the incidence of cauda equina syndrome at 1% to 5% of all prolapsed lumbar disks. All eight patients undergoing emergency corrective surgery had an acontractile detrusor with no bladder sensation, and four of seven had an inactive sphincter electromyogram. Follow-up urodynamics showed that all still had an acontractile detrusor and three had normal electromyographic activity. Three patients had electromyographic activity, but with denervation potentials in two and low activity in two. The clinical picture in cauda equina syndrome can vary widely, from minimal to maximal sensory and motor involvement.

Spinal Stenosis

Spinal stenosis is a term applied to any narrowing of the spinal canal, nerve root canals, or intervertebral foramina. It may be congenital, developmental, or acquired. Compression of the nerve roots or cord by such a problem may lead to neuronal damage, ischemia, or edema. Spinal stenosis may occur without disk prolapse. Symptoms may range from those consequent to cervical spinal cord compression to a cauda equina syndrome, with corresponding urodynamic findings (Smith and Woodside, 1988). Back and lower extremity pain, cramping, and paresthesias related to exercise and relieved by rest are the classic symptoms of lumbar stenosis caused by lumbar spondylosis and are believed to result from a sacral nerve root ischemia. The urodynamic findings are dependent on the level and the amount of spinal cord or nerve root damage. Deen and coworkers (1994) reported subjective improvement in over 50% of such patients with bladder dysfunction who were treated by decompressive laminectomy. In cervical spondylitic spinal stenosis, detrusor overactivity or underactivity may occur, depending on whether the primary pathologic process affecting the micturition neural axis is compression of the inhibitory reticulospinal tracts or myelopathy in the posterior funiculus, which carries proprioceptive sensation (Tammela et al, 1992). Because there is no consistent pattern of dysfunction with any type of spinal stenosis, urodynamic studies again should serve as the cornerstone of therapy. In a study of 26 patients undergoing urodynamic assessment of spinal stenosis preoperatively and postoperatively, substantive improvements were noted in postvoid residual volume, maximal cystometric capacity, and flow rate postoperatively after successful surgical intervention in all patients. Urodynamic evaluation was important from a diagnostic standpoint to identify patients who were experiencing LUT compromise (Cong et al, 2010). Podnar and colleagues (2006) assessed 65 cauda equina patients with neurologic examination, electromyography, and urodynamics. Severe LUT dysfunction was noted in 14% of women and 15% of men, whereas moderate dysfunction was noted in 27% of men and 46% of women. Incomplete emptying was the most common symptom (>90%), and urinary incontinence was next with 56% of men and 71% of women. Reduced capacity was noted in 9% and 15%, respectively. Poor detrusor contractility was noted in 59% of men and 85% of women. Using multiple linear regression, perianal sensory loss and female gender had the most significant positive predictive value for urinary incontinence.

Radical Pelvic Surgery

The inferior hypogastric plexus (pelvic plexus) which innervates the viscera of the pelvic cavity is a paired structure located on the side

of the rectum in males and at the sides of the rectum and vagina in females. LUT dysfunction after pelvic plexus injury occurs most commonly after abdominoperineal resection (APR) and radical hysterectomy. The true incidence of neurogenic vesicourethral dysfunction after various types of pelvic surgery is unknown because there are few prospectively studied series of patients with preoperative and postoperative urodynamic evaluation. The incidence has been estimated to range from 20% to 68% of patients after APR, 16% to 80% after radical hysterectomy, 20% to 25% after anterior resection, and 10% to 20% after proctocolectomy (Blaivas and Chancellor, 1995b). These are estimates drawn from past literature, and the current incidence is most likely significantly lower, owing to the use of nerve-sparing techniques during these types of pelvic procedures. It has been estimated that the LUT dysfunction remains permanent in 15% to 20% of affected individuals (McGuire, 1984; Mundy, 1984). The injury may occur from denervation or neurologic decentralization, tethering of the nerves or encasement in scar, direct bladder or urethral trauma, or bladder devascularization. Adjuvant treatment, such as chemotherapy or irradiation, may compound the damage. The type of LUT dysfunction that occurs is dependent on the specific nerves involved, the degree of injury, and any pattern of reinnervation or altered innervation that occurs over time (see Chapter 69 and the previous section on neuroplasticity). Therapeutic and disease-related effects on pelvic nerves have substantive effects on long-term functional outcomes after treatment for anal-rectal carcinomas. Approximately one third of patients have some element of urinary tract dysfunction (urinary frequency, urgency, and/or poor detrusor contraction resulting in retention and incomplete emptying). This can be related to surgical, radiotherapeutic, and chemotherapeutic effects. Abdominoperineal resection has the greatest impact on function, most likely because of autonomic nerve injury at time of resection. Other dysfunctions related to sexual activity, ejaculatory dysfunction in men, and vaginal dryness and dyspareunia in women are also commonly associated with the management of this malignancy (Lange and van de Velde, 2011).

Literature on the effects of parasympathetic decentralization on neuromorphology and neuropharmacology of the LUT in many animal models is abundant (Wein and Barrett, 1988).

Parasympathetic decentralization has been reported to lead to a marked increase in adrenergic innervation of the bladder in some experimental models, with the resultant conversion of the usual β (relaxant) response of the bladder body in response to sympathetic stimulation to the α (contractile) effect (Sundin et al, 1977). Hanno and colleagues (1988) confirmed that, in the cat model, parasympathetic decentralization does result in adrenergic hyperinnervation of the detrusor but that pelvic plexus neurectomy alone or parasympathetic decentralization plus hypogastric neurectomy yields no detectable increase in adrenergic innervation. In their experimental model, decentralization did result in synaptic reorganization in bladder wall ganglia with new cholinergic excitatory inputs from the hypogastric nerves. Koyanagi was the first to call attention to what he referred to as supersensitivity of the urethra to α -adrenergic stimulation in a similar group of patients with neurologic decentralization of the LUT, implying a similar change in adrenergic receptor function in the urethra after parasympathetic decentralization (Koyanagi et al, 1988). Nordling and colleagues (1981) described a similar change in women after radical hysterectomy and ascribed this change to damage to the sympathetic innervation of the LUT.

When permanent LUT dysfunction occurs after radical pelvic surgery, the pattern is usually one of impaired bladder contractility or a failure of the bladder to voluntarily contract. Urodynamically, obstruction may be seen from likely residual fixed striated sphincter tone, which is not subject to voluntarily induced relaxation. Often, the smooth sphincter is open and nonfunctional. Whether this appearance of the bladder neck and proximal urethra is caused by parasympathetic damage or terminal sympathetic damage or whether it results from the hydrodynamic effects of obstruction at the level of the striated sphincter is debated and unknown. Decreased compliance is common in these patients,

and, with the “obstruction” caused by fixed residual striated sphincter tone, may result in both storage and emptying failure. These patients often experience leakage across the distal sphincter area and are unable to empty the bladder, because, although intravesical pressure may be increased, they cannot mount a true bladder contraction. The patient often has urinary incontinence that is characteristically and most commonly initiated with increases in intra-abdominal pressure. This is usually most obvious in women, because the prostatic bulk in men often masks an equivalent deficit in urethral closure function. Alternatively, patients may have variable degrees of urinary retention.

Urodynamic studies may show decreased compliance, poor proximal urethral closure function, loss of voluntary control of the striated sphincter, and a positive bethanechol supersensitivity test, findings similar to those in Figure 75-4. Upper tract risk factors are related to intravesical pressure and the detrusor leak point pressure, and the therapeutic goal is always low-pressure storage with periodic emptying. In men, the temptation to perform a prostatectomy should be avoided unless a clear bladder outlet obstruction is demonstrated at this level. Otherwise, prostatectomy simply decreases urethral sphincter function and thereby may result in the occurrence or worsening of sphincteric urinary incontinence.

We strongly urge caution in the early postoperative period, because the temptation to “do something” other than perform CIC initially after surgery in these patients is often strong, especially in those patients with little or no preexistent voiding dysfunction. Most of these dysfunctions will be transient, and our general practice in these patients is to discharge them on CIC with full urodynamic evaluation at a later date. Frequently, 6 to 12 months may elapse before detrusor function returns to an acceptable level (Blaivas and Chancellor, 1995b). Many of the changes after radical pelvic surgery are similar to those seen in sacral cord injury or disease. In an excellent study on decreased bladder compliance after decentralization, Sislow and Mayo (1990) noted a higher prevalence of this finding in patients who had undergone radical pelvic surgery than in those who had sustained conus medullaris or cauda equina injury.

Questions remain as to whether nonradical pelvic surgery such as simple hysterectomy can be ultimately responsible for storage or emptying abnormalities on the basis of neurologic damage. At this time there is no consensus opinion, and more series that include sophisticated preoperative and early and late postoperative urodynamic evaluation are necessary.

There is, as yet, no clear consensus as to the independent effects of childbirth and hysterectomy on LUT function. A variety of explanations have been put forth regarding whether or not, in fact, LUT dysfunction is induced by these events and, if so, what the underlying pathophysiology may be. In a multicenter Danish trial (Gimbel et al, 2005), a total of 319 women with benign disease were randomized to undergo either total abdominal hysterectomy (158) or subtotal abdominal hysterectomy (161). At 1-year follow-up after intervention, urinary incontinence was less often noted in patients undergoing total abdominal hysterectomy. Both groups, however, did experience an increase in incomplete emptying requiring double voiding. It is interesting to note that both groups experienced an overall decrease in urinary incontinence frequency as compared with baseline.

To date, there have been no prospective trials documenting a long-term follow-up relationship between urinary dysfunction and method of delivery, and no prospective clinical trials have been done to determine if cesarean section is protective against the development of incontinence. The debate regarding cesarean section as an alternative to spontaneous vaginal delivery and impact of each on the LUT also continues. The Epidemiology of Incontinence in the County of Nord-Trøndelag (EPINCONT) study assessed 15,307 women for the development of voiding dysfunction during longitudinal follow-up. The risk of urinary incontinence of all types was noted to be higher in women who had had cesarean sections as compared with nulliparous women and those who had had vaginal deliveries. However, the risk of moderate-to-severe incontinence

was actually less in patients who had undergone cesarean sections than in those who had delivered vaginally. Urgency incontinence was the only exception, being equal across all groups. The adjusted ratio for any incontinence in women after cesarean section was 1.5 versus 1.7 for women with vaginal deliveries. Stress incontinence appeared to be associated with mode of delivery (Rortveit et al, 2003a, 2003b).

McKinnie and associates (2005) studied 1004 women over an 18-month period to determine the relationship between urinary and fecal incontinence and type of delivery. In this study, pregnancy increased the overall risk of urinary and fecal incontinence, and there was no apparent relationship to mode of delivery.

Simple and Radical Hysterectomy

In a study of the effects of hysterectomy on LUT function, 430 women who underwent either vaginal or abdominal hysterectomy for benign conditions (without prolapse as an indication) were assessed. Patients completed validated questionnaires before surgery and up to 10 years after surgery. Significant differences were noted between the vaginal and abdominal approaches in terms of symptoms as measured by the Urogenital Distress Inventory and Defecation Distress Inventory questionnaires. Women who underwent hysterectomy by the vaginal approach were more likely to have micturition symptoms as compared with abdominal approach patients (18% vs. 8%). In addition, defecation symptoms also appeared to be more common after vaginal hysterectomy (58% vs. 46%) (Sultan and Thakar, 2006; Lakeman et al, 2011). As compared with simple hysterectomy, radical hysterectomy may have more debilitating effects on bladder and bowel function. In a study of 209 patients undergoing radical hysterectomy for malignant disease with a survey return rate of 32% (66 of 209) (Brooks et al, 2009), 42% of patients undergoing radical hysterectomy reported mild incontinence symptoms as compared with 50% of controls. Moderate symptoms were seen in 34% of subjects and 35% of controls. Moderate-to-severe symptoms were noted in 18% of subjects and 14% of controls. Fecal symptoms did not differ between subjects and controls. Radical hysterectomy in this group did not appear to be associated with more long-term bladder or anorectal dysfunction (Brooks et al, 2009).

Herpesvirus Infections

Invasion of the sacral dorsal root ganglia and posterior nerve roots with herpes zoster virus may produce urinary retention and detrusor areflexia days to weeks after the other primary viral manifestations (Rytto et al, 1985). In general, painful cutaneous eruptions secondary to the virus are also present, but initially the patient may have only fever, malaise, perineal and thigh paresthesias, and obstipation. Urinary incontinence secondary to detrusor overactivity may also occur, but the pathophysiology is unclear. It may be related to nerve root irritation, inflammation of the meninges or spinal cord, or "zoster cystitis" (Broseta et al, 1993). Cystoscopy may reveal vesicles in the bladder mucosa similar to those seen on the skin. Spontaneous resolution usually occurs in 1 to 2 months. Out of 57 patients with herpes zoster infection, 15 (26%) showed urologic manifestations, but only 2 had frank urinary retention (Broseta et al, 1993). Three patients demonstrated urinary incontinence, and all 3 demonstrated detrusor overactivity on urodynamics. Ten patients demonstrated irritative storage symptoms with dysuria and frequency.

Out of 423 patients admitted with a diagnosis of herpes zoster LUT, 17 (4%) had voiding dysfunction (Chen et al, 2002). Excluding those with cranial rather than spinal nerve involvement, the incidence was 8.8%; however, when only patients with lumbosacral dermatome distribution were considered, the figure rose to 28.6%. The authors subdivided the bladder disorders into three types. Twelve of the 17 affected patients (71%) had voiding dysfunction caused by herpetic cystitis and had dysuria, frequency, retention, pyuria, or hematuria on presentation. Four of the 17 patients (24%) had neuritis-associated voiding dysfunction, presumably affecting

the sacral motor neurons, and on presentation had urinary retention with a "flaccid bladder." One patient had myelitis-associated voiding dysfunction with spinal cord involvement, with detrusor overactivity on presentation. All 17 patients regained a normal or "balanced bladder" within 8 weeks, and no major urologic sequelae were noted.

Urinary retention has also been reported to occur in association with anogenital herpes simplex virus infection. Caplan and colleagues (1977) reported 11 such patients with the typical clinical picture of herpes genitalis, all of whom developed urinary retention 2 to 7 days after the genital eruption. Three such patients showed pleocytosis of the cerebrospinal fluid, a finding that Hemrika and associates (1986) believed was indicative of CNS involvement. They termed the coexistence of bilateral involvement of the sacral nerve roots of rapid onset accompanied by sphincteric incontinence with cerebrospinal fluid pleocytosis the *Elsberg syndrome* and tabulated 47 such cases reported before their article. Haanpaa and Paavonen (2004) added 2 patients, both of whom had transient urinary retention but developed chronic neuropathic pain in the sacral area. As with herpes zoster, the LUT dysfunction was transient.

Diabetes Mellitus

Diabetes is the most common cause of peripheral neuropathy in Europe and North America. The exact prevalence of diabetes in the United States is between 1% and 6%, depending on whether one includes only diagnosed patients and on what fasting blood glucose criteria are used for inclusion (the higher estimate of prevalence represents a recent reduction in blood glucose criteria to 126 mg/dL) (Chancellor and Blaivas, 1995a; Goldman and Appell, 2000a). The clinical spectrum of LUT dysfunction thought to be caused by diabetes has been extensively reviewed by a number of authors, each of whom has cited the same historical articles up to their date of publication and added their personal experience at that time (Kaplan and Blaivas, 1988; Beck et al, 1994; Chancellor and Blaivas, 1995a; Kaplan et al, 1995; Wein and Rovner, 1999; Goldman and Appell, 2000a). The exact incidence of LUT dysfunction caused by diabetes is uncertain; however, 5% to 59% of patients with diabetes report symptoms of LUT dysfunction. In attempting to estimate the true incidence and types of LUT dysfunction specifically associated with diabetes, one has to carefully discriminate between articles that consider patients referred for voiding symptoms versus those that have evaluated unselected patients from a population known to have diabetes. In the Nurses' Health Study, urinary incontinence was found to be more prevalent in women with diabetes (8.7% vs. 5.3% of controls). The odds of urinary incontinence developing increased by 20% with diabetes. The predominant type of associated incontinence noted in this study was urge incontinence; no association between diabetes and stress incontinence was recognized (Danforth et al, 2009).

KEY POINT: DIABETES MELLITUS

- Cai Frimodt-Moller (1976) coined the term *diabetic cystopathy* to describe the involvement of the LUT by this disease. The classic description of voiding dysfunction secondary to diabetes is that of a peripheral and autonomic neuropathy that first affects sensory afferent pathways, causing the insidious onset of impaired bladder sensation. As the classic description continues, a gradual increase in the time interval between voiding results, which may progress to the point at which the patient voids only once or twice a day without ever sensing any real urgency. If this continues, detrusor distention, overdistention, and decompensation ultimately occur. Detrusor contractility, therefore, is classically described as being decreased in the end-stage diabetic bladder. More recently, however, detrusor overactivity has been cited as the most frequent urodynamic finding. This could be a result of a difference in the time of diagnosis with reference to the natural history of the effects of diabetes on the LUT.

Current evidence points to both a sensory and a motor neuropathy as being involved in the pathogenesis, with the motor aspect contributing to the impaired detrusor contractility. **The classic urodynamic findings include impaired bladder sensation, increased cystometric bladder capacity, decreased bladder contractility, impaired uroflow, and, later, increased residual urine volume.** At least in men, the main differential diagnosis is bladder outlet obstruction, because both conditions commonly produce a low urinary flow rate; however, pressure-flow urodynamic studies easily differentiate the two. **Smooth or striated sphincter dyssynergia usually is not seen in classic diabetic cystopathy,** but these diagnoses can easily be erroneously made on a poor or incomplete urodynamic study (e.g., voiding may involve abdominal straining, which will produce an interference electromyographic pattern [pseudodyssynergia], and abdominal straining alone will not open the bladder neck area).

Other authors have suggested that findings seen in classic diabetic cystopathy may not represent the predominant form of LUT dysfunction. In a group of 19 female and 4 male elderly diabetic nursing home patients with symptoms of urinary dysfunction, 61% were found to have involuntary bladder contractions, 17% to have voluntary contractions of decreased magnitude, and 13% to have normal detrusor contractility, and 9% were unable to initiate a detrusor contraction at all (Starer and Libow, 1990). In another group of diabetic patients referred because of voiding symptoms, Kaplan and coworkers (1995) found that 55% had involuntary bladder contractions, 23% had impaired detrusor contractility, 10% had detrusor areflexia, and 11% had "indeterminate findings." Of the 42 patients with sacral cord neurologic signs, 50% had impaired detrusor contractility and 24% had detrusor areflexia. Chancellor and Blaivas (1995a) detailed the urodynamic findings in 43 diabetic patients at Chancellor's institution, with 33% having involuntary bladder contractions with normal contractility, 23% having involuntary bladder contractions with impaired contractility but were able to void, 9% having impaired bladder contractility alone but were able to void, 23% having detrusor areflexia, and only 12% having a normal urodynamic study. Ueda and associates (1997) also found involuntary bladder contractions in a moderate percentage of diabetic patients (25%), but noted that all these patients had a history of cerebrovascular disease and that no patient had involuntary bladder contractions who did not have such a history. Although it is obvious that some (or even many) of the patients with diabetes who exhibited involuntary bladder contractions may have had factors other than diabetes to account for their bladder overactivity, the importance of urodynamic study in diabetic patients before the institution of therapy cannot be overemphasized.

A variety of animal models have been able to replicate the diabetic state; however, different models demonstrate different patterns of disease expression. These and a discussion of potential pathophysiologic mechanisms involved in effects of diabetes on LUT function are found on the Expert Consult website.

Early institution of timed voiding will avoid some of the impaired detrusor contractility from chronic distention and detrusor decompensation. Experimental studies are currently directed at inhibiting the proposed mechanisms by which hyperglycemia produces neuropathy (Clark and Lee, 1995). Ayan and colleagues (1999) cite references showing that intensive therapy for diabetes can slow its progression and slow the development of abnormal autonomic tests. On a short-term basis, the authors showed that insulin therapy in alloxan-induced diabetic rabbits prevented the urodynamic effects (e.g., increased bladder capacity and compliance) and histopathologic changes seen in a similar but non-insulin-treated group of animals. Insulin reversed most of the changes reported by Cardozo and coworkers (2002). Despite improvement in other organ systems with enhanced glycemic control, LUTS in patients with type 1 diabetes do not appear to respond well to other otherwise well-documented glycemic control (Van Den Eeden et al, 2009).

A recent prospective evaluation of women with type 2 diabetes assessed urodynamic findings as compared with responses to A δ

and C fibers in the bladder using intravesical current responses to threshold frequencies at 250 and 5 Hz, respectively. Of the 86 women evaluated, 34.9% had detrusor underactivity, 14% (12) had detrusor overactivity, 12.8% (11) had bladder outlet obstruction by the criteria of the trial, and 38.4% (33) had normal detrusor function. With the normal detrusor function group used as a comparator, the underactivity group showed not only decreased emptying capabilities, but also decreased sensation on both cystometry and intravesical current perception threshold testing. The overactivity group demonstrated impaired storage and emptying function but had no significant changes in intravesical current reception. In this trial, an increase in current perception threshold values was associated with a decrease in bladder voiding efficiency at both 5 and 250 Hz. These data underscored the evidence that impaired A δ - as well as C-fiber function had direct effect on bladder pathways for emptying in patients with diabetes mellitus (Lee et al, 2009).

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is a **potentially life-threatening, inflammatory demyelinating disorder of the peripheral somatic and autonomic nervous system.** It is described as a recognizable clinical entity characterized by rapidly evolving symmetrical limb weakness, loss of tendon reflexes, absent or mild sensory signs, and variable autonomic dysfunctions (Hahn, 1998). It results from aberrant immune responses directed against peripheral nerve components (Hartung et al, 1995; Hahn, 1998) and is triggered by a preceding bacterial or viral infection, with the immune responses directed toward the infecting organisms cross-reacting with neural tissues. The immune reactions against Schwann cell surface membrane or myelin result in acute inflammatory demyelinating neuropathy (accounting for 85% of cases), whereas reactions against axonal membrane components cause acute motor-sensory axonal neuropathy, accounting for the remaining 15%. Two thirds of patients report an antecedent acute infectious illness, most commonly a respiratory tract infection or gastroenteritis that has resolved by the time the neurologic symptoms begin. Several anecdotal case reports have linked GBS to vaccination by temporal association alone. About 75% of cases reach their nadir within 2 weeks, and 94% within 4 weeks. After a brief plateau phase, paralysis gradually resolves over weeks to months. In general, the outcome is favorable, but Hahn (1998) quotes a mortality rate of 5% to 8% despite the most aggressive management. **Autonomic neuropathy is a common complication.** Cardiac arrhythmia, hypertension and hypotension, and bowel, bladder, and sexual dysfunction may occur. **The prevalence of LUT dysfunction ranges from 25% to over 80% (Wyndaele et al, 2005).** Zochodne (1994) reviewed multiple series and reported a urinary retention rate of 11% to 30%. Of the 7 of 28 GBS patients with voiding dysfunction, 3 had transient urinary retention; 2 had urgency, nocturia, and urge incontinence; 1 had stress incontinence; and 1 had otherwise unexplained voiding difficulty (Sakakibara et al, 1997a, 2009). Although many of these patients may have an indwelling catheter in the acute setting, **their voiding dysfunction should be managed by reversible therapy** (e.g., CIC, anticholinergic therapy) pending resolution. The urinary symptoms associated with GBS are multifaceted. In other reports, approximately 27% of patients with GBS have demonstrated urinary symptoms, with urinary retention being present in 9.2% of patients. Defecatory dysfunction and urinary dysfunction are highly related to the motor grade of GBS symptomatology. Antibody titers have no relationship to symptomatic urinary dysfunction. The most common urinary findings include increased postvoid residual volume, followed by decreased bladder sensation, detrusor overactivity, diminished bladder compliance, and underactive detrusor contraction, as well as sphincteric dyssynergia. These findings underscore the difficulty in prediction of LUTS based on condition diagnosis only (Sakakibara et al, 2009). In another study of GBS patients, 38 patients were assessed using Hughes motor grading, Overall Disability Sum Score (ODSS), and Medical Research Council (MRC) sum score with urodynamics at baseline and at 2 months. Ten of 38 patients had urinary symptoms; 23 of the 38 had

Alloxan-induced diabetic rats demonstrate detrusor overactivity, whereas sucrose-fed rats demonstrate normal bladder contractions. In addition, streptozotocin-induced diabetic rats more commonly demonstrate pyuria, raising the question of an inflammatory component. Therefore the type of model used should be considered when attempting to interpret experimental findings (Yoshimura et al, 2003). Liu and Daneshgari (2005) concluded that the bladders of diabetic and diuretic rats weighed more than control animals and that diabetes and diuresis caused a significant increase in overall fluid intake, urine output, and bladder size. An increased response after field stimulation was noted in both diabetic and diuretic conditions and a reduced response to cholinergic activity was noted as compared with controls. The authors noted that this finding indicated the possibility of neurogenically mediated bladder contraction in the diabetic rat. Numerous authors have proposed potential pathophysiologic mechanisms that could account for the various types of voiding dysfunction seen in diabetic patients. Clark and Lee (1995) describe the basic mechanism of interference with physiologic mechanisms as increases in blood glucose increasing the intercellular accumulation of both glucose and its subsequent metabolic products. Hyperglycemia is then proposed to lead to microvascular and neurologic complications, with the neurologic sequelae ultimately resulting in a loss of myelinated and unmyelinated fibers, wallerian degeneration, and blunted nerve fiber reproduction and function. The proposed mechanisms include increased accumulation of polyols (sorbitol) from glucose through the aldolase-reductase pathway, inhibiting both glomerular and neural synthesis of myo-inositol. The decrease in myo-inositol synthesis depresses phosphoinositide metabolism, decreasing Na^+/K^+ -ATPase activity. Hyperglycemia also leads to the formation of advanced glycosylation end products, inhibition of the formation of which in animals has been shown to improve response to functional and structural abnormalities of peripheral nerves. NGF and other nerve trophic factors also appear to play a role in regulation of the pathogenesis of diabetic voiding dysfunction. In addition, nitrergic and adrenergic mechanisms also contribute to the ultimate pathophysiologic cascade of this condition (Torimoto et al, 2009). In another report of streptozotocin-induced diabetic rats, the diabetic condition was associated with increased bladder weight. This was associated with a decreased blood vessel density that occurred on a time-dependent basis. In a comparator group of polyuric animals, similar changes were noted. These findings appeared to support not only direct change, but also diuretic-induced changes as being an additional physiologic consequence of the diabetic condition (Liu et al, 2010).

Another aspect of diabetic bladder dysfunction may occur at the organelle level. In rodent models morphologic changes in chronic diabetes have also included mitochondrial abnormalities, particularly in the urothelium. Increased collagen was noted to be deposited in capillary walls, with an interruption or extensive widening of the gap junctions between myocytes in the bladder muscularis. Reduced mitochondrial counts were noted in the urothelium and bladder muscle. Degenerated nerve fibers and myelin bodies were identified between myocytes, with increased collagen and mast cell inflammatory aggregates noted in the stroma of diabetic rats as compared with nondiabetic controls. The duration of diabetes appeared to amplify these changes, and the authors concluded that diabetic changes were a time-dependent phenomenon (Rizk et al, 2006).

In addition to this overall hypothesis, there are tantalizing “chunks” of data from various investigators that may or may not prove to be involved in the pathogenesis of diabetic voiding dysfunction. In streptozotocin-induced diabetic rats, Hashitani and Suzuki (1996) reported reduced spontaneous spike activity, failure of neuromuscular transmission, reduced potency of the smooth muscle sodium-potassium pump, and the development of a post-junctional, muscarinic supersensitivity, without alteration of the ATP receptor sensitivity. Tong and colleagues (1999) reported an upregulation of M_2 receptor protein in the bladder of streptozotocin-induced diabetic rats and an upregulation of M_2 receptor protein in bladder body tissue (Tong and Cheng, 2002). Presumably, this

could be related to detrusor overactivity and conceivably account for a differential effect of various anticholinergic agents, depending on their receptor specificity. Mumtaz and coworkers (1999) reported an impairment of nitric oxide-mediated urethral smooth muscle relaxation in alloxan-induced diabetic rabbits along with a significant impairment of nonadrenergic noncholinergic nerve-mediated relaxation in this area. They hypothesize that nitric oxide may be functionally inactive and/or unavailable in this type of diabetes, and this lack may contribute to non-benign prostatic hyperplasia (BPH)-related outlet obstruction in patients with long-term diabetes and to detrusor overactivity, although it is a bit unclear as to how changes in only the outlet might influence overactivity. Gupta and colleagues (1996) and Gupta and Wein (1999) suggested that diabetes diminishes sodium pump activity, thereby inhibiting agonist-induced contractions in bladder smooth muscle by an increase in intracellular sodium concentration, the latter acting to diminish calcium influx. In abstract form, Chacko's group (1999) hypothesized a translocation of protein kinase C isoforms as being involved in decreased detrusor contractility in alloxan-induced diabetes in rabbits. Cardozo and coworkers (2002) reported enhancement of bladder contractions to SP and des-Arg-BK in a streptozotocin model. Sasaki and associates (2002) described decreased NGF in bladder tissue and L6 to S1 dorsal root ganglia. In alloxan-induced diabetic animals, Khan and colleagues (2002) noted decreased apoptosis of bladder urothelial cells. In this same model, Su and associates (2004) reported increased myosin light chain phosphorylation and decreased sensitivity to activator calcium. Changolkar and coworkers (2005) reported decreased smooth muscle force associated with increased lipid peroxides and sorbitol and an overexpression of aldolase reductase and polyol pathway activation. Another interesting pathophysiologic explanation is one that is attributed to autoimmune phenomena. Antibody-mediated bladder dysfunction in type 1 diabetes has been identified in a murine model, in which anti-voltage-gated calcium channel antibodies induce urodynamic findings such as phasic detrusor contractions and also loss of bladder wall compliance compatible with overactive bladder. The autoimmune dysfunction was reversed by the administration of agonists for voltage-gated calcium channels. The possible reversibility of this phenomenon remains intriguing for early stage treatment (Wan et al, 2007).

Hyperglycemia-induced oxidative stress in detrusor smooth muscle resulting in microvascular and macrovascular events has been postulated to contribute to urologic symptoms and complications associated with diabetes (Kirschner-Hermanns et al, 2012). In addition, further evidence of oxidative stress has been identified by comparative gene expression studies. When nondiabetic versus streptozotocin-induced-diabetic in animals were assessed for oxidative stress via a variety of protein-based metabolic assays (glutathione and S-transferase activity, lipid peroxidation, and carbonylation and nitrosylation of proteins), global gene expression in the diabetic animals demonstrated a significant increase in markers for oxidative stress. This was subsequently further hypothesized to have a downstream effect on protein damage and apoptosis. This hypothesis was confirmed by demonstrating an increase in protein degradation product (Nedd-4 and LC3B) in diabetic bladders. The conclusion was that oxidative stress resulted in aberration and protein-based pathways resulting directly from oxidative stress (Kanika et al, 2011).

In a trial using rodent (mouse) exposure to streptozotocin in an M_2 muscarinic receptor knockout model as compared with wild-type specimens, the M_2 receptor was found to modulate bladder overdistention associated with streptozotocin-induced neuropathy and therefore preserve function. The difference between function in the wild-type versus the knockout model approximated a 70% difference in those animals with retained M_2 receptors (Pak et al, 2010a). With the same study construct (wild type versus M_2 muscarinic receptor knockout exposure to streptozotocin), rodents were exposed to oxotremorine-M (an M_2 muscarinic agonist). In the wild-type animals, contractile function was maintained by enhanced mediation by M_2 contractile activity despite loss of M_3 activity in these animals (Pak et al, 2010b).

Smooth muscle ultrastructural and functional changes in detrusor smooth muscle associated with streptozotocin-induced bladder dysfunction in mice has been attributed to the contribution of the L-type voltage-operated channels (L-VOCCs). The presence of these receptors and an increased density of M_3 receptors were noted in streptozotocin-induced diabetic animals. The role of these L-VOCC channels continues to be explored ([Leiria et al, 2011](#)).

Therefore, the pathophysiology of diabetic cystopathy can be attributed to five possible sources. Alterations in muscarinic receptor densities specifically with overexpression of M_2 receptors may be one mode of dysfunction. Direct neural damage caused by hyperglycemia resulting in glycosylated end products may accelerate microvascular disease as well as inducing endothelial dysfunction and causing a deleterious effect on nitric oxide release. In addition, the production of sorbitol in a hyperglycemic environment may increase reactive oxygen species, resulting in oxidative stress at the muscle cell level. Hyperglycemia may, as well, increase the production of diacylglycerol, resulting in the activation of protein kinase C, which affects transcription of a variety of connective tissue constituents including type IV collagen, contractile proteins, and fibronectin, as well as damaging local endothelial and neural cells. Finally, there may be a decrease in NGF, which has been previously hypothesized to protect bladder activity ([Nanigian et al, 2007](#)).

urodynamic abnormalities, with the most significant being detrusor underactivity in 15 patients. DSD was found in 6 patients, bladder acontractility in 5, and detrusor overactivity in 3. There was a correlation between disability based on these scoring systems and urodynamic findings (Naphade et al, 2012).

MISCELLANEOUS NEUROLOGIC DISEASES CAUSING LOWER URINARY TRACT DYSFUNCTION

Lyme Disease

The associated neurologic symptoms of Lyme disease (neuroborreliosis) fall broadly into three syndromes: (1) encephalopathy, (2) polyneuropathy, and (3) leukoencephalitis. The Lyme spirochete can also (rarely) invade the bladder itself. Chancellor and colleagues (1993) described seven patients who also had LUT dysfunction. Five had detrusor overactivity, none had dyssynergia, and two had detrusor areflexia. In two women, urinary retention was the presenting symptom of Lyme disease. Other subjective symptoms noted were urgency, frequency, nocturia, and urge incontinence. Follow-up at 6 months to 2 years after treatment revealed residual urgency and frequency in three patients.

Hereditary Spastic Paraplegia

Hereditary spastic paraplegia (HSP) is a genetically transmitted disorder, usually autosomal dominant, less commonly autosomal recessive, and rarely sex linked. There is a pattern of central demyelination with axon loss and progressive lower extremity spasticity with muscle weakness. Bushman and coworkers (1993) described three patients, two of whom had detrusor overactivity (one with striated sphincter dyssynergia), one who had significantly decreased compliance, and one who was urodynamically normal except for a high maximum urethral pressure of uncertain significance. Pure forms of this disease are associated with primary lower extremity spasticity at presentation, but variance exists.

Jensen and colleagues (1998) reported the voiding characteristics of 11 patients with autosomal dominant pure spastic paraplegia linked to chromosome 2p21-p24. These patients were culled from six of eight families with the disorder; the authors commented that LUTS were present in 16 of 44 definitely affected family members. One patient had an indwelling catheter, and thus an accurate description of symptomatology was not possible. For the other patients, urinary urgency and frequency were the dominant complaints, with 6 of these 10 patients regularly experiencing urgency urinary incontinence. Urodynamically, 3 patients showed detrusor overactivity, 6 demonstrated normal detrusor activity, and 1 demonstrated "hyporeflexia" with delayed first sensation. Satisfactory sphincter electromyographic recordings were obtained from 7 patients, and all were normal. Postvoid residual urine volumes were elevated in 8 of 10 patients. The bulbocavernosus reflex was absent in 6 patients and was truly normal in only 1 patient. The authors commented that the frequency of urinary symptoms in their patients (36%) correlated well with other reports in the literature. They proposed that the LUTS (along with bowel and sexual dysfunction) in patients with this disorder are caused by a combination of somatic and autonomic nervous system involvement, supporting a multisystem involvement. LUT dysfunction is well recognized in this condition and is associated with high prevalence rates in those of Eastern European extraction (approaching 77%). In a study of 29 HSP patients, the primary urinary symptom was urgency in 72%, followed by frequency in 65%, incontinence in 55%, and hesitancy in 51%. Urodynamic findings included detrusor overactivity in 51% and sphincter dyssynergia in 66%, with increased postvoid residual volume in 41%. However, there was no significant risk of upper tract complications related to this condition (Fourtassi et al, 2012). In another study of patients with HSP, 49 patients were assessed and 38 (77.6%) had some urinary concern. LUT dysfunction occurred similarly in the pure and complex forms of the disease. The most common symptoms associated with this condition were urinary incontinence of any type (69.4%), urinary hesitancy (59.2%),

increased frequency (55.1%), and associated urinary urgency (51.0%). Incomplete bladder emptying was the least common (36.7% of patients). Increased LUT dysfunction was more commonly associated with the female gender (Braschinsky et al, 2010).

Tropical Spastic Paraparesis

Tropical spastic paraparesis is primarily a spinal cord myelopathy caused by a retrovirus (human T-cell leukemia virus 1 [HTLV-1]) that is similar to human immunodeficiency virus (HIV). Progressive lower limb weakness and back pain are typically the primary complaints, but LUT dysfunction occurs in up to 60% of those affected (Walton and Kaplan, 1993). Eardley and associates (1991) studied six such patients with LUT dysfunction. Two had detrusor areflexia and three had overactivity, one of whom also had dyssynergia. Walton and Kaplan (1993) found that four of five consecutive patients had detrusor overactivity and DSD, whereas one had overactivity and synergy. The type of voiding dysfunction depends on whether the damage is primarily to the descending spinal tracts, to the sacral nuclei, or to the sacral outflow. The disease must be distinguished from other myelopathic conditions associated with LUT dysfunction, such as MS.

Acquired Immunodeficiency Syndrome

Infection with HIV can affect both the central and the peripheral nervous systems, and so it is not unexpected that symptoms of LUT dysfunction occur. As with many other conditions, there is some disagreement as to the overall prevalence of such symptoms in this population. AIDS-related neurogenic voiding dysfunction is associated with a poor outcome, with a mortality rate of approximately 40% within 8 months of development of urologic symptoms (Heyns and Fisher, 2005). Khan and coworkers (1992) were among the first to report on the types of LUT dysfunctions seen in 11 patients with AIDS. Urinary retention occurred in 6, whereas on urodynamic evaluation, 3 had detrusor overactivity, 4 had detrusor areflexia, 2 had a hypocontractile detrusor, and 2 had outlet obstruction secondary to BPO. In a prospective study of 39 patients with HIV infection and voiding symptoms, clinical symptoms included frequency, urgency, and incontinence in 41% of patients, acute urinary retention in 28%, dysuria and frequency in 18%, and decreased flow in 13% (Hermieu et al, 1996). Seventeen of the patients had involuntary bladder contractions, and, of these, 8 had DSD or a lack of sphincter relaxation during micturition, 5 had detrusor areflexia, 4 had what was termed a "hypertonic urethra," 3 had "hypersensitivity," and 5 had a normal urodynamic evaluation. The authors characterized the voiding dysfunctions broadly as inability to void in 41% of the cases and frequency, urgency, or incontinence in 41%. Furthermore, the authors proposed that the appearance of neurogenic voiding disturbances heralded a poor prognosis. Eighteen HIV-positive patients, 13 with acquired immunodeficiency syndrome (AIDS), with voiding dysfunction were urodynamically characterized by Kane and coworkers (1996). Chief presenting complaints were daytime frequency in 8 patients, retention in 3, nocturia in 2, and having to strain to void, feeling incompletely empty, and having incontinence, a split stream, or groin pain in 1 each. Five patients (28%) showed detrusor overactivity, 5 showed DSD, and 1 (6%) showed detrusor areflexia. The authors remarked that there is a correlation among cytomegalovirus infection, polyradiculopathy, and detrusor areflexia, a phenomenon reported by others as well. Lima and colleagues (2002) evaluated a group of 26 men with HIV-induced bladder dysfunction. Eighty percent of those patients demonstrated detrusor overactivity, and 34% had detrusor-sphincter dyssynergia. These findings are indicative of the myopathy associated with HIV (Lima et al, 2002). Other common causes of LUT dysfunction exist as well; 5 patients had outlet obstruction, 4 secondary to BPO and 1 from urethral stricture. The fact that HIV can cause demyelination at any site in the nervous system complicates symptom-based management of the HIV-infected patient and mandates sufficient LUT evaluation as a guide for therapy (Delgado et al, 2014). Renal functional

impairment may result from LUT dysfunction or from primary renal involvement by the disease (Tonolini et al, 2013). Gyrtrup and colleagues (1995) prospectively investigated voiding function in 77 men and 4 women with HIV infection or AIDS consecutively attending an outpatient clinic. Eight of these (10%) had moderate subjective voiding problems, whereas two (2%) had severe problems. The authors believed that in only 4% of patients did the nature of the disturbance warrant urodynamic examination and concluded that urinary voiding symptoms are only a modest problem overall in an HIV/AIDS population. They concluded that neuropathic bladder dysfunction is rare and occurs mostly in the late stages of the disease.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is an acute inflammatory demyelinating disorder of the CNS of unknown cause. It is also sometimes known as *parainfectious* or *postinfectious encephalomyelitis*. The locations of lesions are multifocal and can include the cerebral white matter, cerebellum, brainstem, and spinal cord. Of 11 patients with ADEM, 9 had urinary retention; the other 2 had urgency, frequency, nocturia, and difficulty voiding (Sakakibara et al, 1996b). One patient in the latter group had enuresis and urgency incontinence as well. The urodynamic findings are difficult to correlate with the presenting symptoms, because in 4 of the patients the studies were done considerably after the onset of the disease. During the follow-up period, 7 of the 9 patients who originally had retention became able to urinate. Five had difficulty voiding, and four developed irritative symptoms. Six of the patients ultimately had a near-complete neurologic recovery, but voiding symptoms persisted in 3. The authors concluded that the supranuclear and nuclear types of pelvic and pudendal nerve dysfunction were primarily responsible for the micturitional disturbances in patients with this disease and that voiding dysfunction was very common in these patients.

Syringomyelia

Syringomyelia is a chronic disorder of the spinal cord characterized by dissociated sensory loss and brachial amyotrophy. It usually affects the cervical spinal cord but can extend caudally. LUT dysfunction has been reported in 9% to 25% of patients. Fourteen patients with syringomyelia were studied urologically by Sakakibara and associates (1996c). Eleven of these had urinary symptoms: difficulty voiding in 8, retention in 3, nocturnal and daytime frequency in 3, incontinence in 2, and urgency and enuresis in 1. The urinary symptoms appeared from 2 months to 13 years after the initial neurologic symptoms. Urodynamic studies revealed detrusor overactivity in 7, DSD in 4, detrusor areflexia in 4, and "uninhibited sphincter relaxation" in 2. It is interesting that motor unit electromyographic recordings disclosed findings compatible with denervation of the striated sphincter in 5 of 6 patients. The authors concluded that both supranuclear and nuclear types of peripheral autonomic and somatic nerve dysfunction are responsible for the LUT dysfunctions seen. It is also interesting that the micturitional status gradually improved in 4 of 6 patients after syringosubarachnoid shunts.

Schistosomal Myelopathy

Schistosomiasis may cause LUT dysfunction from bladder neck obstruction and impaired muscle contractility as a result of infiltration of the bladder smooth muscle itself. In addition, it can rarely cause spinal cord involvement, either as a granulomatous intrathecal mass or as an acute transverse myelitis (Razdan et al, 1997). Two such patients had urinary incontinence as their chief urologic complaint, and both had detrusor overactivity, 1 without dyssynergia and with minimal motor weakness and 1 with DSD and a T11 sensory level. It was believed that the findings in the former patient were characteristic of a partial spinal cord or cerebral lesion and that the second patient had a suprasacral transverse myelopathy. In the first patient, the urinary symptoms developed approximately 2

months after exposure and after the development of systemic symptoms, whereas in the second case, symptoms developed some 5 years after the initial diagnosis. Gomes and associates (2002) reviewed the records of 14 patients with schistosomal myelopathy referred because of LUT dysfunction. Of 5 patients with acute disease, 3 had retention and 2 had incontinence. Urodynamics were performed in 3 of these. Two (1 in retention, 1 with hesitancy and incontinence) demonstrated detrusor areflexia, and 1 (with retention) showed detrusor overactivity and DSD. Of the 9 patients with chronic disease, 5 showed detrusor overactivity with DSD, 1 had decreased compliance, 2 had overactivity with synergic sphincters, and 1 had detrusor areflexia with decreased compliance. In another study of 26 patients with schistosomiasis, all patients had chronic neurologic and urologic symptoms secondary to this diagnosis. The most common urinary symptoms were difficulty in bladder emptying in 65% of the patients followed by incontinence in 54% and urgency and frequency in 50% of the patients, UTI in 30% of patients, and bilateral hydronephrosis in 19%. Detrusor overactivity associated with sphincter dyssynergia was present in 54% of the patients, with detrusor areflexia being present in 23% of the patients. Patients with dyssynergia had a much higher incidence of upper tract decompensation. These findings are consistent with classically defined involvement of spinal cord as a common complication of this disease (Gomes et al, 2005).

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a disease with a likely autoimmune origin in which there is widespread inflammatory change in the connective tissues and small vessels of the skin and systemic organs (Hahn cited by Sakakibara et al, 2003b). The prevalence of nervous system involvement ranges from 18% to 75%, and myelopathy occurs in 1% to 3% of SLE patients. Sakakibara and associates (2003b) reported on eight patients with SLE with LUT dysfunction, six with voiding difficulty (two of whom had retention), and four with urinary incontinence. Five exhibited decreased flow, three had increased residual urine, five had detrusor overactivity, five had impaired detrusor contractility, four had DSD, and two of four patients studied exhibited abnormal striated sphincter electromyographic potentials. Sensation was impaired in two. Although three patients had subacute encephalomyelopathy (one subacute myelopathy, four chronic myelopathy), the LUT dysfunction seemed to have been related mainly to the myelopathy.

Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy (RSD) is a disabling syndrome characterized by severe pain with autonomic changes, such as vasomotor disturbances. The condition usually follows a traumatic injury; the exact cause and pathogenesis are unclear. The prevalence of LUT dysfunction in patients with RSD is unknown, but it must be more than a rare occurrence because Chancellor and colleagues (1996) were able to collect 20 consecutive patients with neurologically verified RSD who were referred because of new-onset voiding symptoms. Seven of the patients had urinary retention, although some of these had undergone various types of surgery designed to treat the symptoms of the dystrophy. Five presented with urgency incontinence, one of whom also had stress incontinence. Six had urgency as a primary complaint, 1 had daytime frequency, and 1 had severe nocturia. Detrusor overactivity was demonstrated in 8 patients, DSD in 1, detrusor areflexia in 8, and hypersensitivity on filling in 3. Because the authors excluded patients who acutely developed voiding dysfunctions after back surgery and those with herniated disks, one must conclude that significant LUT dysfunction can develop as a direct result of, or in association with, RSD. However, the cause-and-effect relationship is so far unclear.

Tuberculosis

Spinal tuberculosis has been associated with significant evidence of micturition disturbances including high postvoid residual volume

and urinary symptoms. In a recent assessment of patients undergoing clinical urodynamics and spinal MRI, 30 spinal tuberculosis patients were assessed; 15 had some form of micturition disturbance (urinary incontinence or storage disorder). Four of the 15 also demonstrated retention; 2, stress incontinence; 6, urinary hesitancy; 11, urgency; and 9, urge incontinence. These symptoms were associated with a significant incidence of either paraparesis or quadriparesis (13 patients). Detrusor overactivity with high-pressure voiding was present in 6. Detrusor areflexia was present in 4, with the remainder having increased postvoid residual volumes. After intervention, those patients with prior micturition disturbances had poor functional recovery as compared with patients without micturition disturbances. There was a strong relationship between bladder symptomatology and severity of paraplegia, horizontal sensory level, and signal abnormality in the cord; these variables were associated with poorer outcome than in those patients without them (Kalita et al, 2010).

MISCELLANEOUS CONDITIONS DEFINITELY, PROBABLY, OR POSSIBLY RELATED TO NEUROMUSCULAR DYSFUNCTION

Detrusor Sphincter Dyssynergia

Dyssynergia refers to the kinesiological disassociation of two groups of muscles that, in general, work in harmony. *Sphincter dyssynergia* refers to an involuntary contraction, or lack of relaxation, of either the striated sphincter (the striated muscle surrounding the proximal urethra and the striated muscle that forms a part of the urethra for a variable distance from the “urogenital diaphragm” to the bladder neck) or the smooth sphincter (the smooth muscle of the bladder neck and proximal urethra). *Detrusor sphincter dyssynergia*, unless specified otherwise, refers to dyssynergia of the striated sphincter and is sometimes abbreviated DSD or DESD. This is discussed in Chapter 70 and in the earlier parts of this chapter, especially in the section on SCI. It is discussed as a separate entity here as well to emphasize its importance in terms of recognition and proper management in patients with neurogenic voiding dysfunction.

True DSD should exist only in patients who have an abnormality in pathways between the sacral spinal cord and the brainstem PMC and is usually caused by neurologic injury or disease (Blaivas, 1982; Rudy, 1993; Chancellor and Rivas, 1995; Wein and Rovner, 1999). The diagnosis of DSD should be suspected in any patient with a neurologic lesion in this area. Common causes include traumatic SCI, MS, and transverse myelitis. Conversely, in patients without such a lesion, this diagnosis should always be viewed with skepticism, and, without such apparent pathology, such a patient deserves exhaustive study to exclude a neural diagnosis. One exception to this precept is in infants and children with dysfunctional voiding or the Hinman syndrome (see later).

Blaivas and coworkers (1981) have described three categories of DSD. In type 1 there is a concomitant increase in both detrusor pressure and electromyographic activity; at the peak of the detrusor contraction, the sphincter suddenly relaxes and unobstructed voiding occurs. In type 2 there are sporadic contractions of the striated sphincter throughout the detrusor contraction. In type 3 there is a crescendo-decrescendo pattern of sphincter contraction that results in outlet obstruction throughout the entire detrusor contraction. Schurch and colleagues (2005) have correlated neurologic status and DSD type after SCI and found that those with an incomplete sensory and motor lesion typically have type 1 DSD, whereas those patients with complete sensory and motor lesions have type 2 and type 3. Weld and associates (2000) prefer to classify DSD as intermittent or continuous, but note that in their experience the clinical significance of DSD type is not crucial because both types require urodynamic surveillance and expedient treatment to minimize complications. No significant association between type and level of injury was found; however, continuous DSD was more associated with complete injuries.

It is important to remember that sphincter electromyographic activity that increases simultaneously with intravesical or detrusor pressure does not always indicate true DSD. These instances are referred to as *pseudodyssynergia* (Wein and Barrett, 1982), and such a misdiagnosis may be accompanied by adverse therapeutic consequences. Common causes of pseudodyssynergia include (1) abdominal straining to either initiate or augment a bladder contraction or in response to discomfort, and (2) attempted inhibition of a bladder contraction either because of its involuntary nature or because of discomfort. Rudy (1993) reported that pseudodyssynergia can reliably be differentiated from true DSD urodynamically by analyzing the patterns of detrusor and electromyographic activity, but others have not consistently found this to be the case.

Without proper treatment, over 50% of men with DSD will develop significant complications, such as VUR, upper tract deterioration, urolithiasis, urosepsis, and ureterovesical obstruction (Chancellor and Rivas, 1995). In women, these complications are much less common, most likely a result of the lower detrusor pressures generated. Using Blaivas's categorization, type 1 DSD is usually managed with observation alone unless there is persistent VUR, hydronephrosis, or autonomic hyperreflexia, whereas types 2 and 3, in general, require treatment. In assessing success or failure of treatment, Kim and colleagues (1998) used bladder leak point pressure greater than 40 cm H₂O as an indicator of the failure of sphincterotomy, because in their experience there was a significantly higher incidence of upper tract damage and persistent DSD in such patients. This most likely applies to other treatments as well. Therapy for DSD is designed to either eliminate or significantly minimize the abnormal sphincter activity or to bypass the sphincter itself. Oral medical therapy directed toward the striated sphincter has not enjoyed wide success. The most common treatment approaches currently are (1) CIC (usually combined with therapy to control detrusor overactivity), (2) sphincterotomy, (3) stent placement across the sphincter, (4) injection of onabotulinumtoxinA into the sphincter, (5) continuous indwelling catheterization, and (6) urinary diversion.

Dysfunctional Voiding

Dysfunctional voiding is more extensively considered in Chapter 143 but is mentioned here because individuals with a history of unexplained LUT dysfunction symptomatology may not be seen by the urologist or be definitively diagnosed with this entity until adulthood. This syndrome, also described by various authors as *non-neurogenic neurogenic bladder*, *occult voiding dysfunction*, *occult neuropathic bladder*, *learned voiding dysfunction*, and *Hinman syndrome*, demonstrates what urodynamically appears to be involuntary obstruction at the striated sphincter level existing in the absence of demonstrable neurologic disease (Hinman, 1986). It is very difficult to prove urodynamically that an individual has this entity, and it should further be noted that the diagnoses in many of the patients reported have been made on the basis of only history, isolated flowmetry, isolated measurements of total intravesical pressure, and pelvic floor electromyographic activity (Wein and Barrett, 1988). Unequivocal demonstration of this entity requires pressure-flow electromyographic evidence of bladder emptying occurring simultaneously with involuntary striated sphincter contraction in the absence of any element of abdominal straining, either in an attempt to augment bladder contraction or as a response to discomfort during urination. Such reports do exist and confirm the existence of this syndrome. The cause is uncertain and may represent a persistent transitional phase in the development of micturitional control or persistence of a reaction phase to the stimulus of LUT discomfort during voiding, long after the initial cause of the problem has disappeared (Jorgensen et al, 1982).

Bladder Neck Dysfunction

Bladder neck dysfunction is defined here as an incomplete opening of the bladder neck during voluntary or involuntary voiding. It

has also been referred to as *smooth sphincter dyssynergia*, *proximal urethral obstruction*, *primary bladder neck obstruction*, and *dysfunctional bladder neck*. The term *smooth sphincter dyssynergia* or *proximal sphincter dyssynergia* is usually used when referring to this urodynamic finding in an individual with autonomic hyperreflexia. In male patients with autonomic hyperreflexia, the neurologic pathophysiology is clear. The term *bladder neck dysfunction* more often refers to a poorly understood, non-neurogenic condition first described over a century ago but first fully characterized by [Turner-Warwick and associates in 1973](#). The dysfunction is found almost exclusively in young and middle-aged men, who characteristically report long-standing voiding and storage symptoms ([Webster et al, 1980](#); [Norlen and Blaivas, 1986](#); [Wein and Barrett, 1988](#); [Trockman et al, 1996](#); [Yamanishi et al, 1997](#)). These patients have often been seen by many urologists and have been diagnosed as having psychogenic voiding dysfunction because of a normal prostate on rectal examination, a negligible residual urine volume, and a normal endoscopic bladder appearance. The differential diagnosis also includes anatomic bladder neck contracture, benign prostatic enlargement (BPE) or BPO, dysfunctional voiding, prostatitis, neurogenic micturition dysfunction, and low pressure and low flow (see later). Objective evidence of outlet obstruction in these patients is easily obtainable by urodynamic study. Once obstruction has been diagnosed, it can be localized to the level of the bladder neck by video-urodynamic study, cystourethrography during a bladder contraction, or micturitional urethral profilometry (see Chapter 73). The diagnosis may also be made indirectly by the urodynamic findings of outlet obstruction in the absence of urethral stricture, prostatic enlargement, and DSD. [Noble and associates \(1994\)](#) cite the incidence of concomitant involuntary bladder contractions or decreased compliance as 50%; [Trockman and colleagues \(1996\)](#) quote it as 34%.

The exact cause of this problem is unknown. Some have proposed that there is an abnormal arrangement of musculature in the bladder neck region, such that coordinated detrusor contractions cause bladder neck narrowing instead of the normal funneling ([Bates et al, 1975](#)). The occurrence of this problem in young, anxious, and “high-strung” individuals, and its partial relief by α -adrenergic blocking agents, have prompted some to speculate that it may in some way be related to sympathetic hyperactivity. When prostatic enlargement develops in individuals with this problem, a double obstruction results, and [Turner-Warwick \(1984\)](#) has coined the term *trapped prostate* to describe these patients. Because the lobes of the prostate cannot expand the bladder neck, they expand into the urethra. In general, a patient so affected has a lifelong history of voiding dysfunction that has gone relatively unnoticed because he has always accepted this as normal, and exacerbation of these symptoms may occur during a relatively short and early period of prostatic enlargement. Although α -adrenergic blocking agents provide improvement in some patients with bladder neck dysfunction, definitive relief in men is best achieved by a bladder neck incision. In patients with this and a trapped prostate, marked relief is typically effected by a small prostatic resection or ablation that includes the bladder neck, or a transurethral incision of the bladder neck and prostate. Such patients often note afterward that they have “never” voided as well as after their treatment.

Bladder Outlet Obstruction in Women

The female counterpart of male non-neurogenic bladder neck dysfunction is rare but does exist. **Bladder outlet obstruction in women in general is uncommon.** [Diokno and coworkers \(1984\)](#) were among the first to clearly define this entity in women on the basis of video-urodynamic studies. [Nitti and coworkers \(1999\)](#) evaluated the video-urodynamic studies of 261 of 331 women who underwent multichannel studies for non-neurogenic voiding dysfunction. They defined *bladder outlet obstruction* as radiographic evidence of obstruction between the bladder neck and the distal urethra in the presence of a sustained detrusor contraction of any magnitude, which is usually associated with reduced or

delayed urinary flow rate. Obstruction at the level of the bladder neck was diagnosed when the bladder neck was closed or narrowed during voiding. Obstruction of the urethra was diagnosed as a discrete area of narrowing associated with proximal dilatation. Strict pressure-flow criteria were not used to classify cases as obstructed or not obstructed. Using these criteria, the authors found 76 (23%) of their cases to be obstructed and of those, only 12 (16%) were diagnosed as having primary bladder neck obstruction (the counterpart to non-neurogenic bladder neck dysfunction in the male). Thirty-three percent of the cases of obstruction were caused by dysfunctional voiding, 28% by cystocele, 14% by obstruction created by prior incontinence surgery, 4% by urethral stricture, 3% by uterine prolapse, and 1% each by urethral diverticulum and rectocele. [Groutz and associates \(2000\)](#) defined obstruction as a persistent low, noninvasive maximum flow rate less than 12 mL/sec on repeated study combined with a detrusor pressure at maximum measured flow rate of more than 20 cm H₂O in a pressure-flow study. Of the 587 consecutive women referred for urodynamic evaluation of voiding symptoms, only 38 (6.5%) met these criteria of bladder outlet obstruction. Of those, only 3 women (8%) were characterized as having primary bladder neck obstruction. Ten women (26%) had obstruction on the basis of prior anti-incontinence surgery, 24% because of severe genital prolapse, 13% because of urethral stricture, 5% because of dysfunctional voiding, 5% because of true DSD, and 3% because of urethral diverticulum; in 16% there was no identifiable cause. Most authors would agree that surgical treatment of this problem in women should be approached with caution because sphincteric incontinence is a significant risk. [Smith and Appell \(2006\)](#) commented on the importance of urodynamics in distinguishing dysfunctional voiding versus bladder neck dysfunction. They commented on the importance of evaluation inclusive of symptom assessment, uninstrumented uroflow patterns, simultaneous urodynamic and EMG assessment of voiding, as well as the addition of fluoroscopy to assess function of the bladder neck during voiding. They further stressed multidisciplinary therapy including pelvic floor therapy (biofeedback), behavioral modification, and the addition of pharmacotherapy.

Low-Pressure and Low-Flow Voiding in Younger Men: Bashful Bladder

Low-pressure and low-flow voiding can be the result of a number of causes, most notably a decompensating detrusor (usually from bladder outlet obstruction—see Chapters 73 and 104) or as a part of the syndrome known as *detrusor hyperactivity with impaired contractility* (DHIC—see Chapters 73 and 88). When this occurs in a young man, it is usually characterized by frequency, hesitancy, and a poor stream. The entity is readily demonstrated on urodynamic assessment and with no coexisting endoscopic abnormality. The patient usually notes marked hesitancy when attempting to initiate micturition in the presence of others, and some have therefore described this condition as an “anxious bladder” or a “bashful bladder.” The estimate of the incidence of this problem in younger male patients referred for urodynamic assessment varies from 6% ([Barnes et al, 1985](#)) to 19% ([George and Slade, 1979](#)).

[Barnes and associates \(1985\)](#) suggested that, psychologically, these men tend to be obsessional rather than anxious. They suggest that these individuals have a lifelong tendency to over-control the process of micturition and are thus vulnerable to LUTS under stress. The authors recommend that a behavioral modification program be considered. [Rosario and colleagues \(2000\)](#) performed ambulatory urodynamic studies on 40 consecutive symptomatic men with a mean IPSS of 19 who were unable to “perform” during conventional video-urodynamic study. They concluded that a surgically correctable cause of the symptoms could be found in only 20% of men, and only in those 40 years of age and older. They concluded that the contribution of ambulatory urodynamic monitoring in such cases in men younger than 40 years was negligible. As with previous studies, these authors thought that a significant proportion

of such nonobstructed cases would respond to drug therapy or behavioral intervention.

Urinary Retention: Fowler Syndrome in Young Women

Although urinary retention is encountered fairly commonly in men with anatomic obstruction from BPE, urinary retention in women is unusual, but not rare. As in men, the potential causes are classically cited as neurologic, pharmacologic, anatomic, myopathic, functional, and psychogenic. A comprehensive review and algorithm for evaluation and treatment of the various causes of urinary retention in women has been published by Smith and coworkers (1999).

Fowler syndrome (Fowler et al, 1988; Noble et al, 1994; Fowler, 1999; Swinn and Fowler, 2001; Fowler, 2003) refers specifically to urinary retention in young women in the absence of overt neurologic disease. The typical history is that of a woman younger than 30 years who has found herself unable to void for a day or more with no urinary urgency but increasing lower abdominal discomfort. A bladder capacity of over 1 L with no sensation of urgency is necessary for the diagnosis. There are no neurologic or laboratory features to support a diagnosis of any neurologic disease. MRI scans of the brain and the entire spinal cord have been reported to be normal. However a recent MRI assessment of patients with Fowler syndrome has suggested exaggerated cortical procontinence behavior attributable to increased afferent activity emanating from the urethra inhibiting bladder afferents at the sacral level. This increased afferent activity is partially modulated by successful sacral neuromodulation resulting in decreased overall sphincteric activity (Griffiths and Fowler, 2010).

On concentric needle electrode examination of the striated muscle of the urethral sphincter, however, Fowler and associates described a unique electromyographic abnormality. This abnormal activity, localized to the urethral sphincter, consists of a type of activity that would be expected to cause inappropriate contraction of the muscle. Sphincter activity consists of two components: complex repetitive discharges and decelerating bursts. This abnormal activity impairs sphincter relaxation. These patients often have polycystic ovaries, raising the possibility that the activity is linked in some way to impaired muscle membrane stability. This, in turn, allows direct spread of electrical impulses throughout the muscle, possibly from a hormonal abnormality. Thus, the disorder may possibly be the manifestation of a focal, hormonally dependent "channelopathy." This would potentially explain why the condition is seen only in premenopausal women. Efforts to treat this condition by hormonal manipulation, pharmacologic therapy, or injections of onabotulinumtoxinA have been unsuccessful. This condition is highly responsive to neuromodulation, with a success rate approaching 70% even in women who have had urinary retention for many months or years.

The urodynamic finding is detrusor acontractility; however, the same electromyographic abnormality is found sometimes in women with obstructed voiding. This type of electromyographic activity is not uncommon; FitzGerald and associates (2000) cite an incidence of 8% in a series of women undergoing routine urodynamic and electromyographic studies, but its correlation with complete retention is relatively rare.

In one of the largest reports of Fowler syndrome, 247 women with a presumptive diagnosis of Fowler syndrome were assessed. Overall, the diagnosis was confirmed in 57.5% of patients. However, distressingly, in 32% of the patients the authors were not able to determine an ultimate diagnosis. Of the study group, 4.8% had congenital intestinal pseudo-obstruction (associated in some patients with ingestion of high-dose opiates). Other cases of voiding dysfunction included detrusor failure (1.6%), pain or structural abnormality in the LUT (1.6%), recurrent obstruction after surgery for sphincteric incontinence in 1.2%, and a neurologic abnormality other than Fowler syndrome in 1.2% of patients. The authors based their diagnosis on the classic Fowler syndrome (nonpainful urinary retention in women 20 to 35 years of age); patients frequently had polycystic ovaries and relatively mild LUT dysfunction. They further

identified urodynamic findings including a very high urethral closure pressure (greater than 100 cm H₂O) and increased sphincter volume based on ultrasonographic assessment, perhaps suggesting a hormonal-based effect on channel receptors. The authors reported a success rate of 40% to 68% for peripheral nerve evaluation with neuromodulation, followed by a 60% complete success rate after formal implantation and an additional 14% partial success rate in their population. The possibility of autonomic dysfunction as being contributory to this condition was also raised (Kavia et al, 2006).

De Ridder and colleagues (2007) reported 62 women who underwent sacral nerve stimulation, 30 of whom had findings compatible with Fowler syndrome and 32 with idiopathic retention. Somatoform disorder was found in 26% of the Fowler syndrome patients and 43.8% of the idiopathic group. Depression was also higher in the Fowler syndrome group (30% vs. 18.8%). Neither of these findings, however, had correlation with outcome. Nine patients with Fowler syndrome (compared to 19 patients without Fowler syndrome) failed neuromodulation. The authors concluded that Fowler syndrome was actually a positive predictive factor for SNS response in patients with female urinary retention.

Postoperative Urinary Retention

Postoperative urinary retention is a well-recognized but poorly understood event. Its incidence is usually quoted to be 4% to 25% overall. It occurs more frequently after LUT and perineal, gynecologic, and anorectal surgery. In the placebo arms of four trials of adrenergic blocker prophylaxis after these types of surgery, the incidence of postoperative retention ranged from 18.8% to 57% (Velanovich, 1992). Although not mutually exclusive, contributing factors include the following:

1. Traumatic instrumentation
2. Bladder overdistention
3. Diminished awareness of bladder sensation
4. Decreased bladder contractility
5. Increased outlet resistance
6. Decreased micturition reflex activity
7. Nociceptive inhibitory reflex
8. Preexistent outlet pathology (e.g., BPH)

Anesthesia and analgesia can contribute to factors 2, 3, 4, and 6. The idea of a nociceptive inhibitory reflex initiated by pain or discomfort is an attractive one, because a sympathetic efferent limb could directly affect factors 4, 5, and 6 (see Chapter 69).

Bladder decompression for 18 to 24 hours postoperatively decreased the incidence of retention in patients undergoing joint replacement surgery by 52% versus 27% (Michelson et al, 1988) and 65% versus 0% (Carpiniello et al, 1988), compared with CIC. The incidence of urinary infection with continuous catheterization was no different in the study by Michelson and colleagues (15% vs. 11%) and was less in the study by Carpiello and coworkers (16% vs. 43%), in which CIC was carried out in the recovery room as well. The avoidance of acute bladder overdistention to prevent postoperative urinary retention is supported by the experimental observation of a reduced bladder response to sacral neural stimulation during overdistention (>80% reduction) and, as well, after overdistention (19% reduction) (Bross et al, 1999).

Historically, prophylactic adrenergic blockade with phenoxybenzamine has seemed effective in decreasing the incidence of postoperative retention. Velanovich (1992) performed a meta-analysis on the use of phenoxybenzamine and concluded that this agent reduced the occurrence by 29.1%. In a retrospective review of colorectal patients treated with and without phenoxybenzamine, Goldman and colleagues (1988) found a 54.7% incidence of retention in patients not given this agent versus a 19.2% incidence in those who were. The regimen for those not catheterized preoperatively was 10 mg orally the evening before and 1 hour before surgery, 2 hours after, and 10 mg twice daily for 3 days. For those who were catheterized before the procedure, the regimen was 10 mg twice daily, initiated the day before catheter removal. The mechanism of action is uncertain. If an inhibitory nociceptive reflex is initiated, and this is similar to the sympathetic reflex elicited by

bladder filling (see Chapter 69), the mechanism is likely multifactorial. Alternatively, the drug may act only on the outlet to decrease resistance, which may be pathologically increased by anxiety, pain, and other factors related to surgery. Whether other adrenergic blockers are as effective is uncertain (Cataldo and Senagore, 1991).

Hyperthyroidism

Patients with thyrotoxicosis often have symptoms caused by sympathetic overactivity and autonomic nervous system imbalance. Hyperthyroidism has an association with LUTS, especially in women. Autonomic dysfunction may play a contributory role. In an assessment of 65 newly diagnosed untreated women with hyperthyroidism compared with 62 age-matched controls, the women with hyperthyroidism demonstrated significantly higher mean symptom scores for incomplete emptying, frequency, straining, and overall total symptoms. More than 80% demonstrated high total symptom scores and diminished peak flow rates. In follow-up, LUTS and flow times improved significantly after therapy.

There is no relationship between LUTS and serum thyroid levels, hormone levels, or other hyperthyroid symptoms (Ho et al, 2011). Goswami and associates (1997) reported that 12 of 30 patients (40%) experienced the onset of voiding symptoms 1 to 6 months after the onset of the symptoms of thyrotoxicosis. Four of these patients had enuresis. Of the 5 patients who underwent urodynamic studies, all had reduced flow rates and 4 had a significant postvoid residual volume, 3 of whom had an enlarged bladder capacity and increased perineal electromyographic activity during voiding. The LUT dysfunction and urodynamic abnormalities resolved after resolution of the hyperthyroidism. The bladder symptoms were more common in females than in males. A higher incidence of bladder symptoms was noted in patients with thyrotoxicosis: a 7% incidence of urgency with or without hesitancy and a 1% incidence of enuresis.

Schizophrenia

Bonney and coworkers (1997) proposed that a significant subset of schizophrenic patients have involuntary bladder contractions secondary to brain pathology. In a previous study (Gupta et al, 1995), the same group demonstrated involuntary bladder contractions in 4 of 10 evaluable patients with schizophrenia who were referred because of voiding dysfunction or incontinence. All of these patients had a history of significant childhood incontinence, urge incontinence, bedwetting, and a diminished bladder capacity. In the later report (Bonney et al, 1997), the prevalence of urinary incontinence and related symptoms in a group of chronic schizophrenic patients was compared with a group of comparable patients hospitalized with mood disorders. There was a significantly higher prevalence of urge incontinence (34% vs. 17%) and bedwetting (46% vs. 20%) in the schizophrenic group, whereas there were no significant differences in urinary urgency, overall voiding dysfunction, fecal incontinence, or sexual dysfunction. The hypothesis of a neurobiologic correlation between schizophrenia and the occurrence of involuntary bladder contractions is an intriguing one.

Gastroparesis

Gastroparesis is a condition characterized by symptoms from impaired transit of intraluminal gastric contents into the duodenum in the absence of mechanical obstruction. It may be caused by diabetes, occur after gastric surgery, or be idiopathic. Goldman and Dmochowski (1997) characterized the voiding dysfunction of 17 patients with gastroparesis who were referred because of voiding symptoms, 10 of whom had idiopathic gastroparesis and in 7 of whom the condition was secondary to diabetes. Seven patients had abnormal detrusor contraction and delayed sensation, 5 had poor detrusor function and normal sensation, 3 had normal detrusor function and poor sensation, and 2 had normal detrusor contraction and sensation. There was no difference in the occurrence of the

dysfunctions between the two groups. Predominant symptoms were urinary frequency in 7 and difficulty emptying in 10. Patients with idiopathic gastroparesis were more likely to note difficulty emptying (70%), whereas those with diabetic gastroparesis were more likely to have urinary frequency (71%). The authors postulated an association between idiopathic gastroparesis and bladder dysfunction and proposed that a common autonomic neuropathic syndrome may account for the bladder dysfunction in both the idiopathic and the diabetic forms of this syndrome.

Myasthenia Gravis

Any neuromuscular disease that affects the tone of the smooth or striated muscle of the distal sphincter mechanism can predispose an individual to a greater chance of urinary incontinence after even a well-performed transurethral or open prostatectomy. Myasthenia gravis is an autoimmune disease caused by autoantibodies to acetylcholine nicotinic receptors. This leads to neuromuscular blockade and subsequent weakness in a variety of striated muscle groups. The incidence of incontinence after prostatectomy is indeed greatly increased in patients with this disease (Greene et al, 1974; Khan and Bhola, 1989). In addition, Sandler and associates (1998) reviewed three cases of de novo voiding dysfunction in patients with myasthenia gravis (one woman with intrinsic sphincter deficiency, poor pelvic muscle contractility, and detrusor overactivity; one man with detrusor hyporeflexia who reported urgency and incontinence; and one young woman with an acontractile bladder). The authors add a personal report of a fourth patient with urinary retention from detrusor areflexia. They hypothesize that such autonomic dysfunction in a patient with myasthenia might indicate a unique subset with a worse prognosis.

Isaacs Syndrome

Isaacs syndrome is a rare neurologic disorder characterized by continuous muscle contraction, fasciculations, myokymia, excessive sweating, and elevated creatine kinase level. It is caused by antibodies possibly directed against potassium channels on peripheral nerves and is associated with peripheral neuropathy, autoimmune diseases, malignancies, and endocrine disorders. Tiguet and coworkers (1999) present a case with urinary retention associated with a picture of acute demyelinating neuropathy. Their patient had painful urinary and fecal retention; the urinary retention was thought to be caused by spasm of the periurethral striated sphincter and was diagnosed by an inability to pass a catheter beyond this area. Rectal sphincter spasm was also diagnosed. The condition was treated with plasmapheresis and pharmacologic agents to relax the skeletal muscle. Suprapubic drainage was instituted. The condition subsided, and normal urinary function was ultimately restored.

Wernicke Encephalopathy

Wernicke encephalopathy is a rare but well-documented condition caused by a deficiency in thiamine (vitamin B₁) in both alcoholic and nonalcoholic populations. Pathologic lesions are characteristically distributed periventricularly at the levels of the third and fourth ventricles, including the mammillary body, medial thalamic nucleus, hypothalamus, superior cerebellar vermis, PAG, and mid-brain tegmentum. The two major clinical manifestations of thiamine deficiency involve the cardiovascular and neurologic systems, with the latter manifesting in general as a peripheral neuropathy, also known as Wernicke encephalopathy. The initial symptoms of the polyneuropathy range from burning feet to muscle weakness. Sakakibara and associates (1997b) report a case of a pregnant woman with multiple neurologic manifestations of central and peripheral neuropathy and urgency incontinence, manifesting urodynamically with involuntary bladder contractions and a decreased bladder volume. **Resolution of the urinary symptoms occurred after thiamine replacement.** The authors hypothesized that lesions in the medial thalamic-hypothalamic area and PAG were primarily

responsible for the micturitional disturbance. [Tjandra and Janknegt \(1997\)](#) reported a case of a chronic alcoholic man with seemingly isolated erectile and voiding dysfunction. The emptying complaints correlated with a prolonged void with a peak flow rate of 6.4 mL/sec and an interrupted pattern during flowmetry, suggesting poor detrusor contractility. The erectile dysfunction was determined to be neurogenic, and both resolved with thiamine replacement.

Systemic Sclerosis (Scleroderma)

Scleroderma is a disease of the connective tissue characterized by thickening and fibrosis of the skin, abnormalities of the small arteries, and involvement of the gastrointestinal tract, heart, lung, and kidneys. The pathogenesis is unknown but thought to be caused by overexpression of the collagen gene DNA that contributes to excessive production of collagen in these patients. [Lazzeri and colleagues \(1995\)](#) reported the urodynamic assessment and histologic evaluation of nine such women, of whom five had hesitancy, four had decreased stream, two had frequency and nocturia, and two had suprapubic pain. Four patients had detrusor areflexia, one of whom also had decreased compliance. Another patient with a decreased stream also had decreased compliance. Three of the patients with areflexia demonstrated collagen accumulation on histologic examination of bladder biopsies. The authors reviewed five literature reports of various aspects of LUT function and histology in patients with scleroderma but failed to find a consistent pattern. They hypothesized that the areflexia resulted from impaired neurologic modulation owing to the histologic changes in the detrusor tissue.

Conversely, [Minervini and associates \(1998\)](#) evaluated 23 females with systemic sclerosis and found urodynamic alterations in only 3 of 9 patients who reported urinary symptoms. They were unable to correlate voiding symptoms, urodynamic changes, and the degree of bladder wall fibrosis or visceral involvement. Evidence of autonomic nervous system dysfunction was found outside the urinary tract in 13 of these patients. The authors speculate that when LUT dysfunction occurs, it could be caused by the fibrotic replacement of bladder smooth muscle. However, they did not exclude some degree of autonomic dysfunction, as well.

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome refers to a heterogeneous group of disorders characterized by inherited abnormalities of connective tissue. The main clinical manifestations are skin fragility, skin hyperextensibility, and joint mobility. More than 10 subtypes of the syndrome have been defined based on clinical, genetic, and biochemical criteria. Bladder diverticula have been associated with this disorder, with operative repair characterized by a higher recurrence rate than would ordinarily be expected. [Deveaud and associates \(1999\)](#) reviewed the literature on this subject and reported on one such patient with a large left-sided, nonemptying diverticulum, along with a greatly enlarged bladder capacity and high postvoid residual urine. Simultaneously, they reported a second patient without Ehlers-Danlos syndrome who had a UTI and left pyelonephritis. This patient also reported a decreased force of stream, and evaluation disclosed left VUR with a left (presumably congenital) periureteral diverticulum. The diverticulum enlarged with voiding, and the patient had a large postvoid residual volume. Both patients were successfully treated surgically. The authors thought the tissue from the nonperiureteral diverticulum was more closely related to the pathophysiology of Ehlers-Danlos syndrome, noting the tissue from that diverticulum to be more compliant. They attributed this to changes in the extracellular matrix protein caused by the Ehlers-Danlos syndrome.

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant hereditary multiorgan disease characterized by myotonia and distal muscle atrophy. In addition, this condition in later stages is characterized by

cataracts, endocrine disturbances, mental retardation or dementia, testicular atrophy and infertility, progressive frontal alopecia, and disturbances in cardiac conduction. Although myotonic activity has not been found in the sphincter or pelvic floor, many patients have voiding complaints. [Bernstein and coworkers \(1992\)](#) reported on 10 patients, 8 of whom had urinary complaints by history (4 infrequent voiders, 1 with urgency and stress incontinence, 1 with urge and urgency incontinence, 1 with slight urgency without incontinence, and 1 with obstructive symptoms only in the morning). There were no characteristic urodynamic patterns observed, and urodynamic findings did not correlate particularly well with symptoms. [Sakakibara and associates \(1995b\)](#) also reported LUTS in such patients; however, there is **no characteristic pattern of dysfunction**. Thus, such patients need to be characterized urodynamically before any assumptions are made regarding therapy based on symptoms alone.

Corticobasal Degeneration

Corticobasal degeneration is a rare neurodegenerative disorder of the corticobasal tracts in the cerebral cortex and basal ganglia. The disorder tends to have a unilateral predominance and is most likely present in the supranuclear parasympathetic system. Cortical, extrapyramidal, long-tract, and urinary symptoms are commonly noted in this disease process. [Sakakibara and associates \(2004b\)](#) assessed 10 patients with this disorder and compared them with 11 age-matched controls. As compared with controls, the degeneration patients had more common urinary symptoms (80% of study group). Urinary symptoms usually appeared within 1 to 3 years after onset of the disease and became more common with longer disease duration. Nocturnal frequency tended to be the initial urinary symptom, followed by incontinence, urgency, and frequency. Urodynamic findings included decreased bladder capacity, detrusor overactivity (most common), detrusor hypocontractility, and low compliance in individual patients. DSD was not noted.

Sacral Coccygeal Teratoma

Sacral coccygeal teratoma can produce significant neurolgic dysfunction and can be associated with upper tract deterioration as a result of high-grade reflux and abnormal bladder storage pressures. [Ozkan and colleagues \(2006\)](#) identified 14 patients with sacral coccygeal teratoma, of whom 8 had detrusor overactivity and 2 had underactivity. There was also abnormal urethral sphincteric activity in 54% of the patients and 38% demonstrated DSD. Eleven of 14 patients required CIC for bladder emptying, and 5 required anticholinergics. Six patients had hydronephrosis and 7 had reflux ([Ozkan et al, 2006](#)).

Subacute Combined Degeneration

SACD is a condition arising from vitamin B₁₂ deficiency resulting in degeneration of the spinal cord, frontal cortex, and peripheral nerves. Visual dysfunction is also a prominent finding. The condition is associated with deficient dietary intake (vegetarianism and old age), gut malabsorption, gastrectomy, fish tapeworm infestation, and autoimmune disorders. In a study of eight patients with this condition, multiple nonurologic symptoms were associated with the condition including ambulation problems in addition to joint spasticity. Urinary symptoms represented a mix of storage (five of eight patients), voiding (seven of eight patients), and combined dysfunctions (four of eight patients). Urodynamic evaluation revealed detrusor areflexia in two patients, neurogenic detrusor overactivity in three, and normal studies in the remainder. After treatment with vitamin B₁₂ supplementation, detrusor areflexia improved in two patients, dysfunction improved in three patients completely, and four had partial recovery. MRI findings include T2 hyperintensity in the posterior spinal column and subcortical white matter defects in two patients ([Misra et al, 2008](#)).

Williams-Beuren Syndrome

Williams-Beuren syndrome (WBS) is an autosomal disorder associated with cardiovascular abnormalities, facial changes, cognitive dysfunction resulting in mental retardation, and developmental delay. In a study of individuals with this syndrome, 28 children (16 boys, 12 girls) were assessed with a complete urologic workup including renal functional studies, voiding cystourethrography, and urodynamics; 78% of patients had urinary symptoms (urinary frequency 66.7%, enuresis 50%, and urge incontinence 42%). Fifty percent of patients had urinary tract abnormalities, with bladder diverticula being most common (43%). Urodynamic findings demonstrated detrusor overactivity in 60% of patients and sphincteric dyssynergia with detrusor overactivity in 14%. Decreased cystometric capacity was identified in 28% of patients. The exact site of neural compromise associated with this condition (caused by chromosomal deletion 7q11.23) is unknown (Sammour et al, 2006).

Amyloidosis

Subtypes of amyloidosis are associated with neurologic disorders. Familial amyloidotic polyneuropathy, Portuguese type, has been identified as one of these subtypes. In a study of 54 patients with this condition, generalized muscle atrophy and weakness resulting in impairment of gait capabilities were identified. Autonomic and sensory neuropathy occurred early in the course of the condition. There was early development of gastrointestinal symptoms. With disease progression, marked effects were noted in detrusor contractility (deleterious), thought to be caused by amyloid infiltration of peripheral nerves. In addition, a sensory deficit resulting in chronic overdistention injury was postulated as contributory to this finding. Bladder and sphincteric dysfunction appears to occur in the early stage in this disease and produces a progressive dysfunction with the appearance of stress incontinence in both genders as a result of sphincteric dysfunction. Residual urinary volume increase was related to chronic overdistention (Andrade, 2009).

Machado-Joseph Disease

A variant of spinocerebellar degeneration is spinocerebellar ataxia type 3, otherwise known as Machado-Joseph (MJ) disease. This is the most common hereditary spinocerebellar ataxia dominant disease. It is associated with a defined expansion of the *MJD1* gene from the 14q32.1 chromosome. Symptoms include pyramidal spasticity, extrapyramidal rigidity, athetosis, dystonia, visual movement disorder (ophthalmoplegia), eyelid retraction, amyotrophy, and impairment of global sensory function. In a study of 122 patients with this disorder, 17 (13.9%) experienced LUT dysfunction. The mean age of occurrence of the disease was the mid-fifth decade, with urgency being the predominant symptom in 15 and incontinence found in 9 patients. The most common urodynamic finding was detrusor overactivity in 8 patients, areflexia in 1, and normal contractility in 4. Bladder sensory disorder defined by delayed perceptions was identified in 6 patients. Postvoid residual volumes greater than 100 mL were noted in 9 (Musegante et al, 2011).

Radiation

Vale and associates (1993) summarized their experience with the occurrence of voiding dysfunction after external-beam irradiation. They describe an early radiation reaction most prominent at 4 to 6 weeks, with an incidence as high as 70%. Storage symptoms are most common, and urodynamic studies have demonstrated reduced volume at first desire to void, reduced cystometric capacity, and reduced compliance. These parameters tend to return to pretreatment values by 6 months. Symptoms associated with later radiation effects are less common but may be progressive and intractable. Storage symptoms again predominate, and urodynamic studies, when positive, demonstrate reductions in first desire to void and maximum cystometric capacity, presence of involuntary bladder contractions in up to a third of patients, and

an increase in maximum subtracted detrusor pressure during filling. Historical explanations have concentrated on urothelial injury and ulceration with fibrosis. In an experimental rat model, the authors found a biphasic reduction in compliance, with the first reduction developing at 4 to 6 weeks after irradiation, followed by recovery. A second reduction phase in compliance started at 10 to 12 weeks and persisted. It is interesting to note that only half of the irradiated bladders demonstrated fibrotic infiltration of muscle bundles, and there was no association between the presence of fibrosis and the magnitude of reduction and compliance. Mast cells were more abundant in irradiated bladders than in controls. Electron microscopic studies in the irradiated bladders showed the presence of areas displaying focal degeneration of smooth muscle cells, with these cells demonstrating disaggregation of filaments and, in some cases, cytoplasmic organelles free in the intracellular space. In scattered foci, selective degeneration of unmyelinated axon profiles was noted, ranging from marked to lesser degrees of axonal injury. Thus the authors were unable to confirm a fibrosis-based hypothesis of postirradiation bladder dysfunction in their experimental model, but did reveal other changes that could contribute to such dysfunction (neural degeneration and changes in the detrusor muscle itself).

Choo and colleagues (2002) reported on video-urodynamic parameters in 15 of 17 patients completing studies at baseline and at 3 and 18 months after external-beam irradiation for prostate cancer. Between baseline and 18 months there were no statistically significant changes in detrusor pressure, peak flow rate, voided volume, postvoid residual, compliance, occurrence of detrusor overactivity, or outlet obstruction. There was a mean reduction in bladder capacity of 100 mL in the supine position and 54 mL in the upright position. There was no change in self-assessed qualitative urologic function (IPSS, quality-of-life assessment index, and urinary frequency). There were, however, individual patients who developed decreased compliance (4 patients) and detrusor overactivity (2 patients), urgency (5 patients), and urgency incontinence (3 patients).

The Defunctionalized Bladder

The timing of bladder defunctionalization and the age of the individual at time of defunctionalization may be predictive of bladder functionality. In fetal sheep, urinary diversion results in loss of overall bladder weight with marked connective tissue infiltration and loss of smooth muscle organization. Also, a reduced response to carbachol stimulation and increased response to field stimulation was noted in tissue from animals undergoing early diversion (Matsumoto et al, 2003).

The previously normal defunctionalized bladder will often show decreased capacity and involuntary bladder contractions and/or decreased compliance. Previously abnormal bladders will usually demonstrate their prior pathology, many times with these additional abnormalities. Rehabilitation of a defunctionalized bladder is certainly possible and should definitely be attempted by cycling with progressively increasing volumes. Serrano and associates (1996) considered this subject while evaluating the outcome of transplantation in five long-term defunctionalized bladders. Successful bladder rehabilitation was accomplished, and the transplantation was successful without bladder augmentation, although one patient required CIC. Normal compliance was inferred by the fact that there was no evidence of hydronephrosis after long-term allograft function up to 10 years. The authors proposed that transplantation can be accomplished into a previously defunctionalized bladder when a capacity greater than 100 mL and a voiding pressure less than 100 cm H₂O are demonstrated during bladder rehabilitation. The presence of a defunctionalized bladder may not prevent subsequent renal transplantation. In an assessment of 12 pediatric patients with markedly diminished-capacity (defunctionalized) bladders, transplantation was performed without pretransplant bladder augmentation. The overall transplant survival rates in this group were 100%. Minimal reflux was noted. In addition, all patients were able to void spontaneously without incontinence (Alexopoulos et al, 2011).

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is associated with mixed urinary symptoms. [Davies and colleagues \(2005\)](#) studied 19 women with CAH, of whom 16 had undergone childhood feminizing surgery. Compared with age-matched controls, the CAH population had a higher incidence of urgency incontinence (68%) and stress incontinence (47%). The effects of CAH are uncertain and may be either the result of feminizing surgery secondary to a direct neuropraxia induced by surgery or a primary effect of CAH.

Aging

LUTS and LUT disorders are prevalent and bothersome in the elderly population. These problems are specifically and extensively considered in Chapter 88. When considering the effects of aging on the LUT, one cannot separate the effects of chronologic age itself from the various anatomic, neuromorphologic, neurophysiologic, neuropharmacologic, metabolic, and hormonal changes that coexist with aging, along with the effects of other coexistent disease processes. In addition, neurologic phenomena may masquerade as LUTS associated with bladder outlet obstruction. These phenomena may include multiple cerebral infarctions, cervical spondylosis, and lumbar spondylosis, all findings noted in the Olmsted County longitudinal study and indicative of the need for urodynamics in older men with complex urinary symptoms ([Woderich and Fowler, 2006](#)). In addition to the material contained in Chapter 88, there is an excellent review of this topic by the Committee on Pathophysiology of the Urinary Bladder and Obstruction and Aging for the 4th International Consultation on BPH ([Nordling et al, 2001](#)).

Benign Joint Hypermobility Syndrome

Benign joint hypermobility syndrome has an apparent association with urinary incontinence. [Manning and colleagues \(2003\)](#) prospectively evaluated 1000 women referred for urodynamic evaluation and noted benign joint hypermobility to be associated with increasing bowel dysfunction and a higher degree of urinary tract symptomatology. Also noted was a significant childhood history for both of these phenomena. In a study of 38 women with joint hypermobility as compared with normal controls, symptom questionnaires were administered to both groups; 18 of 30 (60%) with benign joint hypermobility demonstrated urinary incontinence as compared to an incidence of 30% in the controls. In addition, 23% of the women with joint hypermobility also demonstrated anal incontinence as compared to none of the controls. These findings have been attributed to disorders of collagen metabolism; however, the absolute cause has not been clearly delineated ([Jha et al, 2007](#)).

Attention-Deficit/Hyperactivity Disorder

Attention-deficit/hyperactivity disorder (ADHD) occurs in 3% to 5% of children, and LUTS are common in this group. In a study of 75 children with ADHD with voiding dysfunction, all children had daytime enuresis and urgency. In addition, 88% of the children had urinary frequency and 87% had sleep enuresis. Complete resolution of symptoms occurred in 30.4% of patients, and 53.6% had partial response with therapy using a combination of behavior modification and antimuscarinic agents ([Kaye and Palmer, 2010](#)).

Other Conditions

The effect of disordered function of other organs within the pelvis is also potentially contributory to LUT dysfunction. Some of this disordered function may arise as a result of altered afferent neurologic activity induced by other organ disorders. The potential for visceral “crosstalk” has been proposed as a cause of LUT dysfunction and includes syndromes such as interstitial cystitis and irritable bowel syndrome. [Noronha and colleagues \(2007\)](#) assessed the short- and long-term effects of acid-induced colitis on bladder

function in a rodent model. Detrusor muscle contractility and histology were evaluated, both acutely and subacutely after induction of chemical colitis. During the active phase (3 days postinjury), bladder muscle structure appeared histologically normal and inflammation was absent. However, some abnormalities in detrusor muscle contractility in response to electric field stimulation were noted. During the subacute period and after recovery of colitis (15 and 30 days), bladder muscle contractility returned to control levels with no discernible histologic change. These reversible changes were postulated to result from altered afferent input from the colon, resulting in “field” type changes affecting the bladder.

Any neurologic disease or injury can affect LUT function. Many have been mentioned in this chapter, but case reports and small series exist that document many others. The dysfunction produced by some is logically deducible on the basis of similarity to other neurologic lesions. For others, the LUT dysfunctions are inconsistent and seemingly at odds with what would be predicted on the basis of neuroanatomic and neurophysiologic principles. For those who wish to further pursue this subject, the following referenced list may be helpful:

- Adrenoleukodystrophy ([Silveri et al, 2004](#))
- Adrenomyeloneuropathy ([Sakakibara et al, 1998a](#))

TREATMENT OF NEUROGENIC LOWER URINARY TRACT DYSFUNCTION: OVERVIEW

In later chapters, the various therapies available for the treatment of LUT dysfunction are discussed. Only a discrete number of such therapies are available, and these are easily categorized on a functional “menu” basis according to whether they are used primarily to facilitate urine filling and storage or voiding and emptying and according to whether their primary effect is on the bladder or on the outlet (see Table 70-1 and Box 70-3 in Chapter 70).

The initial choice of a mode of management for a given problem is multifactorial, and **certain goals of management for LUT dysfunction are beyond debate (Box 75-1)**. The fact that these goals have remained relatively unchanged over the past few editions of this text attest to their general validity. As a corollary, absolute or relative indications for changing or augmenting a particular regimen

BOX 75-1 Voiding Dysfunction: Goals of Management

- Upper urinary tract preservation or improvement
- Absence or control of infection
- Adequate storage at low intravesical pressure
- Adequate emptying at low intravesical pressure
- Adequate control
- No catheter or stoma
- Social acceptability and adaptability
- Vocational acceptability and adaptability

BOX 75-2 Reasons to Change or Augment a Given Regimen

Upper urinary tract deterioration
 Recurrent sepsis or fever of urinary tract origin
 Lower urinary tract deterioration
 Inadequate storage
 Inadequate emptying
 Inadequate control
 Unacceptable side effects
 Skin changes secondary to incontinence or collecting device

BOX 75-3 Patient Factors to Consider in Choosing Therapy

Prognosis of underlying disease, especially if progressive or malignant
 General health
 Limiting factors: inability to perform certain tasks (e.g., hand dexterity, ability to transfer, body habitus)
 Mental status
 Motivation
 Desire to remain catheter or appliance free
 Desire to avoid surgery
 Sexual activity status
 Reliability
 Educability
 Psychosocial environment, interest, reliability, and cooperation of family
 Economic resources

exist, and, likewise, there is general agreement on these, although the relative importance of the indication for change might be disputed (Box 75-2). It should be remembered that the term *inadequate*, when applied to storage and emptying, applies not only to volumes (capacity, voided volume, residual) but also to unacceptably high detrusor pressures during either or both of the two phases of the micturition cycle. In the planning of goals of therapy and reasons for change, the concept of a “hostility score,” such as that of Galloway (1989), is attractive. His hostility score includes five urodynamic characteristics—bladder compliance, overactivity, dys-synergia, outlet resistance, and VUR. Each is allocated a score of 0, 1, or 2. The best possible score is 0 and implies normal compliance, no inappropriate detrusor activity, a synergic sphincter, a low leak pressure, and no reflux.

The results of treatment of voiding dysfunction are rarely perfect, and they do not have to be. The goals are satisfaction and avoidance of adverse outcomes. A very flexible approach must be adopted in choosing therapy that takes into account the individual wishes of each patient and family and the practicality of each proposed solution for that particular patient (Box 75-3). The therapeutic decisions are thus made with the patient and with the family. In every case, within the limits of practicality, the following should be discussed: reversibility, side effects that occur with some regularity, ultimate best and worst possible scenario, frequency and extent of follow-up, and alternate methods of management. Treatment should always begin with the simplest, most reversible form(s) of therapy, proceeding gradually up the ladder of complexity, but with the knowledge that it is only the patient (and/or family) who is (are) empowered to say when “enough is enough.” Again, satisfaction and avoidance of adverse outcomes are the primary goals. A combination of therapeutic maneuvers can some-

times be used to achieve a particular end, especially if these modalities act through different mechanisms and their side effects are not synergistic or additive. There are circumstances and locales in which health care resources and hospital bed use must also be considered.

The importance of graded intervention for neurogenic disease with the ultimate goals of control of bladder pressures, preservation of renal function, control of UTI, and social continence has been recently underscored by two guidelines (Consortium for Spinal Cord Medicine, 2006; Pannek et al, 2011). Recent consensus guidelines stress the importance of intermittent catheterization as the foundational strategy in the management of the willing and motivated patient or health care provider. Catheterization volumes should be kept below 500 mL (consensus). Credé or Valsalva is not a recommended technique for improving bladder emptying, given concerns regarding outlet resistance. When chronic catheterization is required, suprapubic management is preferable to indwelling urethral catheterization. However, CIC remains the gold standard (EAU guidelines). Recent ICI-RS (International Consultation on Incontinence–Research Society) evaluation of the extant literature on the management of neurologic bladder found that the level of evidence guiding therapy is of poor quality and that more special research is necessary. However, the basis of progressive therapy from medical ascending through surgical is a foundational concept (Wyndaele et al, 2010). Urodynamics may provide a useful guide for directing intervention. Differences in bladder compliance may be predictive of intervention success. Type A (total) versus type C (end fill) compliance patterns respond differently to antimuscarinic management, with resultant impacts on bladder storage pressures and upper tract function (Park and Linsenmeyer, 2001).

Optimal management of the bladder in spinal cord injuries has, in general, focused on the use of CIC where available. In a study of 179 patients undergoing management either with suprapubic or urethral catheterization, both groups had complications related to management technique. Tube revision and incontinence through the suprapubic tract were common in the group so managed. In the urethral management group, urethral erosion and incontinence were also common. The rates of UTI, bladder calculi, and bladder cancer were similar between the two groups (Katsumi et al, 2010). A prospective randomized assessment of spinal cord-injured patients using CIC was recently performed to address the rate of UTI with this condition. The time to first UTI requiring antibiotic management was significantly lengthened in patients using hydrophilic-coated catheters as compared with uncoated catheters. A 33% daily risk for symptomatic infection in those using the hydrophilic catheters was identified. In institutional settings, the use of these catheters reduced infection rate by approximately 21% (Cardenas et al, 2011). Although limited to select male patients, when sphincter ablation is necessary, sphincterotomy using laser treatment is considered the ideal method (however, this is indicated in a very small number of patients) (Linsenmeyer, 2007).

New therapies continue to be proposed for patients with neurogenic LUT dysfunction refractory to medical therapies. The use of dorsal penile or clitoral nerve stimulation for controlled neurogenic detrusor overactivity has been described. Hansen and colleagues (2005) studied a group of 16 patients (2 women and 14 men) with neurogenic detrusor overactivity and diminished bladder capacity associated with complete or incomplete SCI. After stimulation of the dorsal nerve, 13 of 16 were noted to have increased bladder capacity and improved storage pressures during stimulation. The average bladder capacity increase was 53% in the study group. Detrusor pressures were also modulated below those associated with ureterovesical reflux.

Pudendal nerve stimulation has been used for improving neurogenic voiding dysfunction. Spinelli and associates (2005) treated 15 patients with varied types of neurogenic voiding dysfunction. After pudendal stimulation, there was a significant decrease in incontinence episodes, with 8 of 15 patients becoming continent during stimulation, and 2 with improvement approximating 90%. Twelve of 15 ultimately progressed to permanent implantation. In the chronically implanted patients, maximal cystometric capacity

was noted to significantly increase and maximum detrusor pressure was also noted to decrease substantially. Neurophysiologic guidance was considered critical for adequate implantation.

Another form of neuromodulatory therapy for which more experience is being reported in SCI is anterior root stimulation. One of the largest experiences with sacral deafferentation and anterior root stimulator implantation was reported by [Kutzenberger and colleagues \(2005\)](#). A total of 464 paraplegic patients received this intervention, with most patients receiving the intradural approach. At a mean of 6.6 years, 440 of these patients were available for long-term follow-up. Complete deafferentation was successful in 94% of patients; 420 patients used the sacral anterior root stimulator for voiding, and 401 used it for defecation. Overall, 364 (83%) patients were continent. Postoperatively, UTIs decreased from a mean of six to a mean of one and kidney function remained stable in this population. Complications included cerebrospinal fluid leaks in 6 patients and infected implants in 5. In addition, later complications included device failure or cable failure in 35 patients. It is interesting to note that autonomic dysreflexia also disappeared or was resolved in most of these cases. Recently, the Dutch experience with the Brindley bladder stimulator compared with a matched control group was reported; 93 stimulator-implanted patients were compared with a control group of 70 new patients with SCI and neurogenic detrusor overactivity. The main outcomes in the study were quality of life as assessed by the Qualiveen metric. In those patients implanted, long-term stimulators were still used for voiding dysfunction in 63% of the patients (46 patients). Those patients with functional stimulator implants had substantially improved symptom scores and general quality-of-life ratings in addition to improved continence and fewer UTIs as compared with the control group. Apparently, the associated rhizotomy appeared to benefit even patients who had deactivated their stimulator device. The follow-up for these individuals after implant ranged from 1 to 3 years ([Martens et al, 2011](#)).

The future of urinary tract dysfunction related to SCI may be dependent on advances in the use of stem cells for spinal cord repair. However, difference in study type, model used, type of stem cells, and techniques used for stem cell implantation and perpetuation have yet to be standardized for purposes of assessing the potentials of this therapy for impact on long-term urinary function ([Snyder and Teng, 2012](#)).

As a treatment of last resort, urinary diversion may provide significant functional improvement in addition to improved quality of life in selected patients with neurologic dysfunction (e.g., those unable to catheterize). One method for management of incontinence or other refractory storage issues related to neurogenic bladder is bladder neck closure associated with chronic suprapubic catheter management. In a retrospective review of 35 patients undergoing this intervention for a variety of conditions (SCI, 71%; MS, 23%; CVA, 9%) the majority of patients had adequate response to therapy. Only 2 patients were incontinent at follow-up. Overall complications were experienced by 17% of patients ([Colli, 2011](#)). In another assessment of bladder neck closure and suprapubic tube placement, 29 patients were assessed for the efficacy of this intervention (MS, 48%; SCI, 28%; myelodysplasia, 17%). Bladder neck closure was performed via a retropubic approach in most patients at the time of suprapubic tube placement. Eight of 29 patients had persistent incontinence, 2 with peristomal leakage and 6 with urethral leakage. Catheter complications were associated with 7 of the

8 urinary leaks. Perineal bladder neck closure was associated with much higher fistula rates than retropubic approaches. In addition, poor catheter management also resulted in worse success rates ([Ginger et al, 2010](#)). [Stein and colleagues \(2005\)](#) reported on 24 patients undergoing Mainz pouch diversion. Urinary diversion was associated with stability of the upper tracts and daytime continence but with some nocturnal incontinence per stoma. Comparing this group with a separate group of patients undergoing bladder augmentation with suburethral fascial sling, all patients in the augmentation group had stability of the upper tracts and 8 of 10 were continent. Both alternatives were considered adequate for neurogenic voiding dysfunction. Ileovesicostomy also is an option for the management of the neurogenic bladder. In a report of 15 individuals undergoing ileovesicostomy (7 open and 8 robotic), surgical robotic operative times were substantially longer than with open cases; however, there were trends toward less blood loss and shorter hospital stays in the robotic group. With both procedures, there was an improvement in urinary continence from baseline and a trend toward decreased UTI. Overall costs were substantially greater with the robotic versus the open group despite differentials in length of stay. This further underscores the need for further larger studies to assess the possible role of advanced minimally invasive technology for this condition ([Vanni and Stoffel, 2011](#)).

TERMINOLOGY AND DEFINITIONS

The International Continence Society (ICS) Standardization Committee categorized the symptom syndromes suggestive of lower urinary tract dysfunction (Abrams et al, 2002). They stated that urinary urgency, with or without urge incontinence, usually with frequency and nocturia, can be described as the overactive bladder (OAB) syndrome, urge syndrome, or urgency-frequency syndrome if there is no proven infection or other obvious pathology. To be consistent with the individual component lower urinary tract symptoms (LUTS), “urgency incontinence” (Abrams et al, 2009) and “increased daytime frequency” should be in the descriptions used in place of “urge incontinence” and “frequency,” respectively. Thus the current definition of OAB is urinary urgency, with or without urgency incontinence, usually with increased daytime frequency and nocturia, if there is no proven infection or other obvious pathology.

The definitions of the component storage LUTS included in OAB were also standardized by the ICS. Urgency is the complaint of a sudden compelling desire to void that is difficult to defer. It is the OAB symptom with the greatest impact on patients (Milsom et al, 2012). Urgency is an abnormal sensation and should not be confused with the normal sensation of a strong desire to void. Urgency is a term used for sensations reported by patients with OAB, but also by patients with bladder pain syndrome (BPS). The sudden compelling desire to void in these separate patient groups probably differs in character. In OAB, patients may feel as if they are going to leak, even if they say they never have, and they commonly express anxieties exemplified by phrases such as:

- “When I’ve got to go, I’ve got to go.”
- “When I want to go, I have to rush because I think I may wet myself.”

Hence “fear of leakage” is an important concept to OAB patients. In BPS, the compelling desire to void is driven by fear of pain emerging if the bladder is allowed to fill further, but not “for fear of leakage.” In both OAB and BPS, urgency, increased daytime frequency, and nocturia can be present (Fig. 76-1).

Urgency urinary incontinence (UUI) is defined as involuntary leakage of urine, accompanied or immediately preceded by urgency (Abrams et al, 2002). UUI should be diagnosed regardless of whether it causes problems such as social or hygiene effects. In a prevalence survey, 69% of women experienced “any incontinence,” but only 30% found this a “social or hygienic problem” (Swithinbank et al, 1999).

The symptom of increased daytime frequency is the complaint by the patient who considers that he or she voids too often by day. There is no minimum number of voids included in the

standardized definition, and there is currently insufficient research evidence on which to base a threshold for defining increased daytime frequency. The symptom of **nocturia is the complaint that the individual has to wake at night one or more times to void.**

The introduction of the standardized definitions addressed a confusing situation that hampered research and management. The English-speaking world had adopted Patrick Bates’s term *unstable bladder* to describe involuntary detrusor contractions seen during urodynamic studies as the bladder was filled, whereas the Scandinavians used the term *detrusor hyperreflexia*. To resolve the discrepancy, the ICS designated the term *unstable bladder* to be applied where there was no obvious cause for the contractions and *detrusor hyperreflexia* for patients whose involuntary contractions were caused neurologically (Bates et al, 1980a, 1980b). Nonetheless, the use of different terms in neurologic and non-neurologic patient groups became increasingly difficult. “Overactive Bladder” was used as the title of a consensus conference, and a formal definition was proposed in 1999 (Abrams and Wein, 1999), culminating in the unified ICS definition used currently (Abrams et al, 2002). For women, another terminology document, jointly drafted by the International Urogynecology Association and the ICS, was published more recently (Haylen et al, 2010).

The current definition of OAB is based on symptoms; in contrast, detrusor overactivity (DO) is a urodynamic observation, characterized by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked (Abrams et al, 2002). OAB and DO are thus not interchangeable terms, signified by the recognition that OAB patients undergoing urodynamic testing may not have DO (especially continent OAB patients). Conversely DO seen during urodynamics may not be associated with any sensation.

KEY POINTS: OVERACTIVE BLADDER TERMINOLOGY

- The current definition of OAB is urinary urgency, with or without urgency incontinence, usually with increased daytime frequency and nocturia, if there is no proven infection or other obvious pathology.
- OAB is a symptomatic diagnosis and is distinct from DO, which is a urodynamic observation.
- Urgency is an abnormal sensation, defined as the complaint of a sudden compelling desire to void that is difficult to defer.
- “Fear of leakage” and “fear of pain” distinguish urgency in OAB from BPS.

Figure 76-1. Overactive bladder (OAB) and bladder pain syndrome (BPS) both give rise to urgency (U), frequency (F), and nocturia (N); pain, but not urgency urinary incontinence (UUI), is seen in BPS.

PATHOPHYSIOLOGY AND ETIOLOGY

Basic science research into OAB has to use indirect or surrogate markers, because the basis of the condition relies on a subjective symptom of urgency. Thus there is no animal model of OAB, because reporting of subjective symptoms in animals is not possible (Parsons et al, 2011). Accordingly research focus has particularly concentrated on three key aspects: sensory activity, motor control, and reflexes of the lower urinary tract.

- Understanding abnormalities of **sensory nerve (afferent) signaling** is appropriate as it is presumed that urgency sensation largely derives from afferent input. The processes involved are signal transduction, afferent traffic, gating, sensitization, and conscious perception. The role of urothelium and the suburothelial layers of the bladder are now considered substantial contributors to the signal transduction and the afferent traffic through the release of mediators (Birder and Andersson, 2013), cellular interactions (Birder et al, 2010) and release of cytokines and growth factors (Andersson and McCloskey, 2014). Sensitization of bladder nerves by inflammation in the gut innervation has been demonstrated experimentally (Malykhina et al, 2012). Conscious perception is not well understood, but functional brain imaging has highlighted centers in the central nervous system (CNS) that could yield valuable information in the future.
- **Contractile (motor) function** comprises the motility of the detrusor muscle and also relevant drivers—for example efferent nerves, interstitial cells, and locally released mediators. Increasingly the focus has been to evaluate how these aspects summate in the contractility of the whole bladder, which is what determines the urodynamic observations. The whole organ can manifest areas of localized micromotions adjacent to quiescent areas in a constantly changing play of activity (Fig. 76-2). Thus full understanding of intravesical pressure will not be achieved until properties of the overall motile and nonmotile areas can be explained.
- The sensory information ascending in afferents is **integrated at several levels in the CNS** (Drake et al, 2010), where it converges with information from other relevant structures (Fig. 76-3). The integration of this information underpins the coordinated motor behavior of LUT reflexes. In the sacral spinal cord, there is some integration enabling reflex voiding, which is relevant in neonates and in neurologic disease. **The main regulatory region is at the level of the midbrain and brainstem**, where the periaqueductal gray and pontine micturition center integrate the key elements of vegetative function, including the voiding reflex. **At the higher levels of the CNS, more sophisticated aspects are integrated, for example consciousness (LUT sensations, as opposed to subconscious sensory information), awareness of environmental suitability, and voluntary initiation.** There is probably some basic integration in the periphery as well, where interactions may occur between urothelium, interstitial cells, and detrusor muscle (Drake, 2007).

The development of functional brain imaging technology allows estimation of gross activity in specific brain areas and has been used to study bladder filling in normal and symptomatic individuals

Figure 76-2. *Left*, Schematic representation of a whole bladder during urinary storage, illustrating a localized “micromotion” contraction, starting from an initiation point (star), and spreading to a limited part of the bladder wall. Such activity is characteristic of the normal isolated bladder in all species tested (including human), and it is associated with only small fluctuations in bladder pressure (Drake et al, 2003a, 2003b), presumably because the noncontracting part of the bladder stays relaxed. In the overactive bladder (*right*), multifocal trigger points lead to continuous activity; this enhances the effect on bladder pressure (as the bulk of the bladder is active) and stimulates afferents by the extensive distorting movements.

(Griffiths, 2011). Intriguing insights into contributions from various parts of the cerebral cortex such as the insula and the prefrontal cortex have resulted. Alterations in the regional brain activity of symptomatic individuals with OAB have been reported (Griffiths et al, 2007). Understanding brain responses to lower urinary tract activity through autonomic afferent processing networks, as is already under investigation for the gastrointestinal tract, will be crucial in the endeavor to improve insight into the clinical setting.

Afferent Mechanisms in Overactive Bladder and Detrusor Overactivity

In theory, increased sensory activity may give rise to increased sensation, and hence OAB. Thus the properties of the bladder afferents and factors that influence them are highly relevant in OAB. **The afferent nerve endings are widely distributed in the bladder wall and are particularly dense in the connective tissue underneath the urothelium.** The urothelium itself possesses sensory and signaling properties somewhat resembling the characteristics of the afferent nerves. Suburothelial interstitial cells lie in close physical proximity to the nerve fibers, suggesting that these cells may also participate in sensory transduction or its regulation (Wiseman et al, 2003). Accordingly, transduction of sensory stimuli in the bladder into afferent activity probably comes from the interaction of several cell types (Birder and Andersson, 2013).

The afferent nerve fibers include fast-conduction A delta fibers and slower-conducting unmyelinated C fibers. A delta fibers largely respond to passive bladder distention and active detrusor contraction (“in series” mechanoreceptors (Iggo, 1955), thus conveying information about bladder filling (Janig and Morrison, 1986). C fibers are regarded as responding primarily to chemical irritation of the bladder mucosa (Habler et al, 1990) or to thermal stimulus (Fall et al, 1990). Accordingly they may be less active in the physiologic state than the A delta fibers. Nonetheless there is almost certainly considerable overlap in the sensory information carried by the two types of afferent, and the C fibers may take on a more prominent role in pathophysiologic states (Juszczak et al, 2009).

The afferents express a wide range of surface proteins, which may generate or modulate sensory activity. Several members of the transient receptor potential (trp) superfamily are seen on bladder afferents (Avelino et al, 2013), and they provide a tool for studying physiologic properties. One of the best known is the

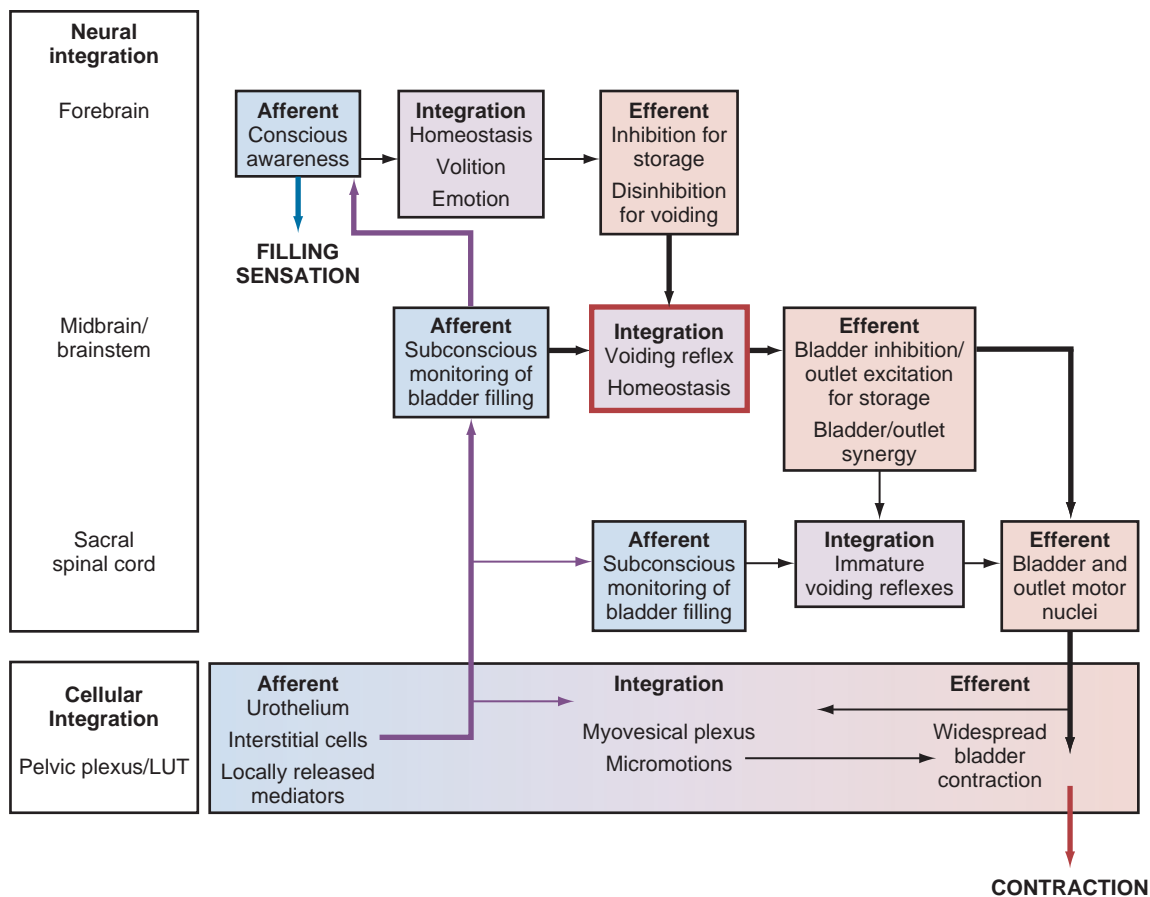

Figure 76-3. Central nervous system circuitry controls the lower urinary tract (LUT) at multiple levels. Sensory information in afferent is affected by peripheral factors, such as mediators and urothelium. It is carried centrally with some input to the sacral cord, which is important for voiding in infants, and it ascends to the midbrain where it inputs to the pontine micturition center (PMC). At this level there is widespread integration of information from vegetative organs, which is crucial for homeostasis. Sensory information is relayed on to the forebrain, where conscious awareness (sensation) is mediated. The forebrain also mediates voluntary control, including the active decision not to pass urine (storage) or to initiate voiding in the right circumstances. Descending forebrain inputs to the PMC allow the switching from storage to voiding phase, with the synergic regulation of the sacral nuclei responsible for bladder contraction and outlet relaxation. There is also possible integration of sensory information in the periphery, contributing to the generation of bladder motility.

vanilloid receptor (trp-V1), which is the target of capsaicin and resiniferatoxin—two compounds previously used for clinical management of neurogenic bladder dysfunction. Purinergic receptors can also influence bladder afferent activity (Munoz et al, 2012). Indeed a range of targets is feasible, but it is unclear whether there are any whose distribution in the body is sufficiently confined so that they could be suitable for treating LUT dysfunction. The trophic influence of growth factors in maintaining the afferent nerves is important physiologically, and some research suggests downregulation of nerve growth factor may mitigate surrogate markers of OAB in animal models (Kashyap et al, 2013).

In theory, OAB may arise if the level of sensory activity is inappropriately high for any given degree of bladder distention, resulting from pathologically sensitized or abnormally numerous afferent nerve endings. The interaction among afferents, urothelium, and interstitial cells is thus interesting, in that modulating their interactions may result in amelioration of symptom severity.

Hypotheses of Detrusor Overactivity

Hypothetical reasoning has been used to conceptualize the clinical observations, particularly for DO. The **neurogenic hypothesis** states that DO arises from generalized, nerve-mediated excita-

tion of the detrusor muscle (de Groat, 1997). Nerve-mediated detrusor excitation is normal during voiding, where it is associated synergically with relaxation of the bladder outlet. However, nerve-mediated detrusor excitation should not occur during urine storage because of inhibitory influences within the CNS. **Emergence of inappropriate excitation during storage implies loss of inhibition, re-emergence of primitive spinal bladder reflexes, acquisition of new reflexes, or sensitization of afferents.** The extent to which inappropriate bladder contraction during storage is associated with outlet relaxation will depend on the precise changes present.

The **myogenic hypothesis** suggests that overactive detrusor contractions result from a combination of an increased likelihood of spontaneous excitation within the smooth muscle of the bladder and enhanced propagation of this activity to affect an excessive proportion of the bladder wall (Brading and Turner, 1994; Brading, 1997). Patchy denervation is a common observation in DO, regardless of etiology (German et al, 1995; Charlton et al, 1999; Drake et al, 2000; Mills et al, 2000). A smooth muscle cell deprived of its innervation shows an upregulation of surface membrane receptors and may have altered membrane potential, which increases the likelihood of spontaneous contraction in that cell. DO is also associated with structural changes (Elbadawi et al, 1993;

Haferkamp et al, 2003a, 2003b), which could facilitate the excessive spread of spontaneous contractions throughout a wider proportion of the bladder than normal. Although the observations in different models of DO and from clinical specimens do not uniformly describe these features, understanding of altered smooth muscle behavior remains a relevant factor for understanding DO.

The integrative hypothesis suggests that a range of triggers can generate localized detrusor contractions, which can spread in the bladder wall through various routes of propagation. Consequently, urgency is a result of distortions in the bladder wall, and it is associated with urodynamic DO if the contractions spread to a sufficient proportion of the bladder wall (Drake et al, 2001). Coolsaet and colleagues (1993) described localized contractions ("micromotions") in pigs, and these contractions were postulated as a basis for urinary urgency. They have been widely reported in normal animals and humans. Importantly, such micromotions are exaggerated in models of DO and in human OAB (Van Os-Bossagh et al, 2001; Drake et al, 2003a, 2003b; Gillespie et al, 2003; Drake et al, 2005). The thinking is that the normal small distortions caused by micromotions are detected by afferents, hence generating the sensation of bladder filling without change in detrusor pressure (see Fig. 76-2). In OAB, the distortions may be excessive as a result of exaggerated micromotions, and they will be associated with DO if the movements become coordinated across a substantial proportion of the bladder. There is considerable overlap between the myogenic and integrative hypothesis, as both allude to the increased peripheral excitability and propagation as key aspects of OAB and DO. The major difference is that the integrative hypothesis exploits the increasing knowledge of cellular physiology in the bladder to draw in the urothelium and interstitial cells as possible contributors in triggering and distributing both normal and pathologic excitation.

Etiology

Female gender is associated with a higher prevalence of OAB, particularly in younger people. A small influence of racial factors is also present; for men, prevalence among African-Americans is 20%, Hispanics 18%, and whites 15%, with the figures for women being 32%, 29%, and 29%, respectively (Coyne et al, 2013).

Neurologic disease is associated with a high prevalence of LUT dysfunction, and this is to be anticipated from the fundamental regulatory influence of the innervation on the bladder and its outlet. Given that most of the time people are storing urine (rather than voiding), it is likely that the CNS exerts continuous inhibitory influence on the bladder contractility. For example, the sympathetic nervous system may inhibit the detrusor muscle directly through β_3 adrenoceptors (Sadananda et al, 2013), or indirectly by inhibiting parasympathetic ganglia (de Groat, 1997). Thus neurologic disease may affect the continuous inhibition, leading to emergence of DO. Aging is clearly associated with increased LUTS, including OAB; the wide range of changes in cellular function and the CNS means that increasing OAB with aging is probably multifactorial. Partial bladder outlet obstruction (BOO) has long been considered an etiologic factor in the generation of DO and OAB, and BOO is a widely used means of generating enhanced nonmicturition contractions as an animal model of DO. However, the relationship between BOO and DO or OAB in humans is not clear-cut. Prevalence of OAB in women, in whom BOO is rare, is broadly similar to that in men in whom BOO is common because of prostate enlargement. Furthermore, DO rarely resolves with prostate surgery. Overall, BOO is probably a relevant factor, but the influence of BOO may be indirect, perhaps by accelerating some of the changes brought on by aging.

The overlap with other functional syndromes and other health influences indicates the need to recognize wider contributory factors to mechanisms underlying the emergence of OAB and its clinical assessment, particularly in relation to bowel function (Daly and Chapple, 2013; Kaplan et al, 2013), metabolic syndrome (Kirby et al, 2010), fibromyalgia (Chung et al, 2013), and hormonal status (Robinson et al, 2013).

KEY POINTS: OVERACTIVE BLADDER PATHOPHYSIOLOGY AND ETIOLOGY

- Sensory nerve activity is influenced by the urothelium and cytokines and is the basis of normal and OAB sensations.
- Efferent nerves and interstitial cells drive bladder contractility; micromotions are normal during the storage phase, but they can become multifocal and exaggerated in OAB.
- Integration of sensory information at multiple levels of the CNS underpins reflex control of the urinary tract, particularly in the midbrain and brainstem.
- The neurogenic hypothesis of DO suggests it arises from generalized, nerve-mediated excitation of the detrusor muscle.
- The integrative hypothesis suggests that a range of triggers can generate localized detrusor contractions, which spread in the bladder wall by various routes; triggering and propagation can occur primarily in the smooth muscle (myogenic hypothesis).
- Aging, neurologic disease, female gender, BOO, and metabolic disease are potential influences on OAB etiology.

PREVALENCE AND COSTS

Using the standardized ICS definition of OAB, the EPIC study (a population-based, cross-sectional telephone survey of adults aged ≥ 18 years in five countries) reported on the prevalence of OAB in four European countries and in Canada, indicating an overall OAB prevalence of 11.8% in the context of a prevalence of 64.3% for at least one of the LUTS (Irwin et al, 2006). The EPIC study also catalogued the multidimensional impact including effects on employment (Coyne et al, 2008b; Irwin et al, 2009). UUI prevalence has been estimated at 1.7% to 36.4% in U.S. populations, 1.8% to 30.5% in European populations, and 1.5% to 15.2% in Asian populations, with the prevalence dependent on age and gender (Milsom et al, 2014). Of 6000 subjects randomly identified from the population in Finland, the presence of any urgency was reported by 54% of respondents (Vaughan et al, 2011). A total of 11% of men and 26% of women reported any UUI. One in seven of all respondents with urgency and fewer than one in three with UUI reported at least moderate bother.

Older studies must be interpreted according to the definitions that the researchers used for LUTS. One prevalence study (Milsom et al, 2001) reported a prevalence of OAB symptoms that "occurred singly or in combination," estimating overall OAB prevalence at 16%. In the studied population, 9.2% experienced urgency, and this is perhaps closer to the true prevalence of OAB in the community.

The National Overactive Bladder Evaluation (NOBLE) study (Stewart et al, 2003) established the prevalence of OAB in more than 5000 community-dwelling individuals in the United States using a validated computer-assisted telephone interview. Men and women had the same prevalence of OAB overall (16.0% and 16.9%, respectively) as defined by the ICS. However, men were shown to have a higher prevalence of "OAB dry" (13.4% as opposed to 7.6% in women) and women had a higher prevalence of "OAB wet" (9.3% as opposed to 2.6% in men). It is assumed that the difference in the prevalence of incontinence is a result of the relative weakness of the bladder neck and the urethral sphincter mechanism in women, particularly in those who have had children, and the additional outlet resistance in men because of the presence of the prostate and the greater urethral length. In women, the prevalence of "OAB wet" rose from 2.0% in the youngest group (ages 18 to 24) to 19.1% in those 65 to 74 years of age. Men, on the other hand, did not experience an increase in "OAB wet" until they were older: 8.22% for those 65 to 74 and 10.2% for those 75 years and older.

The natural history of OAB is varied. Overall there is an increased prevalence of OAB that is associated with aging, and there is progression from "OAB dry" to UUI with the passage of time in

general populations (Irwin et al, 2010). For individuals, OAB can be stable for prolonged periods and remission can occur (Heidler et al, 2011).

In addition to simple prevalence, effects on quality of life need to be evaluated. These effects can occur through wide-ranging influences, for example, increased anxiety levels (Knight et al, 2012) and detrimental impact on sexual function (Cohen et al, 2008; Heidler et al, 2010), and quality of life is also affected by patient attitudes such as the expectation of cure (Renganathan et al, 2010). OAB is a long-term condition, and ongoing quality-of-life impairment can be anticipated in many patients (Garnett et al, 2009).

In some studies, the symptom of urgency was shown to have a greater effect on quality of life than incontinence (Coyne et al, 2004, 2008a, 2008b). EpiLUTS was an Internet-based survey of 30,000 people in the United States, United Kingdom, and Sweden, which documented symptoms, symptom bother, and health-related quality of life. It derived a substantial amount of information about the impact of LUTS, and it identified that storage symptoms were associated with significantly greater impact than other LUTS (Sexton et al, 2009).

Estimates of the overall costs of OAB must be considered with caution, as they depend on the accuracy of prevalence data and the cost components included in the analysis model (Coyne et al, 2014). In 2007, average annual per capita costs of OAB were \$1925, suggesting an overall total national cost in the United States of \$66 billion, of which \$49 billion were direct medical costs (Ganz et al, 2010). Health resource use is increased by indirect impacts, such as impaired productivity (Goren et al, 2014) and falls that occur when patients go to the toilet in urgency situations (Kurita et al, 2013). Costs to the patient include expenditure on containment products and laundry bills.

KEY POINTS: OVERACTIVE BLADDER PREVALENCE AND COSTS

- Overall prevalence of OAB is about 12% in the EPIC study, but estimated prevalence of OAB and UIUI varies widely among studies.
- Aging is associated with higher OAB prevalence in both men and women.
- OAB is generally progressive, but long-term stability and remissions can occur.
- Storage LUTS have a greater impact on health-related quality of life than other LUTS.
- Both genders have similar rates of OAB, but "OAB wet" is more prevalent in women and "OAB dry" is more prevalent in men.
- Substantial expenditure on OAB results from direct and indirect health care costs and patient expenses.

CLINICAL ASSESSMENT

OAB is a syndrome relating several of the storage LUTS, offering an empirical diagnosis that enables health care professionals to initiate preliminary treatment (Abrams et al, 2002). Patients with OAB may present to health care workers in various disciplines in either the community or the hospital services. The American Urological Association/Society for Urodynamics and Female Urology joint Guideline for OAB advocates the clinical principle that the clinician should engage in a diagnostic process to document symptoms and signs that characterize OAB and to exclude other disorders that could cause the patient's symptoms; the minimum requirements for this process are a careful history, physical exam, and urinalysis (Gormley et al, 2012). Because of the relatively nonspecific nature of storage LUTS, it is crucial that physicians consider the possibility of malignancy, neurologic disease or systemic disease. In some patients, additional procedures and measures may be necessary to validate an OAB diagnosis, exclude other disorders, and fully inform the treatment plan (Gormley et al, 2012).

History should cover the following:

1. Presence or absence, incidence, severity, bother, and effect on quality of life for each of the OAB symptoms (urgency, urgency incontinence, increased daytime frequency, and nocturia). Patients with urgency tend to describe frequent voids with a low typical voided volume. Nocturia is somewhat variable in OAB. Voiding and postmicturition LUTS, dysuria, hematuria, and LUT pain should also be assessed. **The most time-efficient and systematic way to explore contributory LUTS is to use a symptom assessment questionnaire.**
2. Nature and volume of fluid intake, recognizing that stimulants and polydipsia affect LUTS, and that patients may adapt their intake to reduce the impact of symptoms.
3. Whether occult neurologic disease could be present; for example, recent onset of OAB with symptoms of erectile dysfunction or tremor.
4. Obstetric and gynecologic history, previous surgery and/or radiotherapy, bowel symptoms, and medication history.
5. Other medical issues (e.g., poorly controlled closed-angle glaucoma, cognitive impairment, history of urinary retention, and impaired gastric emptying are relative contraindications to antimuscarinic therapy).

Focused physical examination requires abdominal and pelvic examination, general examination (e.g., peripheral edema), and basic neurologic examination. Assessment of bladder emptying is necessary (most simply by palpating the lower abdomen if the patient is slim). **Urinalysis is important in all patients** to exclude urinary tract infection, hematuria, and leukocyturia. However, **urodynamics, cystoscopy, and diagnostic renal and bladder ultrasound should not be used in the initial workup of the uncomplicated patient** (Gormley et al, 2012).

The algorithms from the fifth International Consultation on Incontinence (ICI) 2012 (Abrams et al, 2013) summarize the basic assessment necessary in the evaluation of lower urinary tract dysfunction in men, women, and the frail elderly (Fig. 76-4).

Instruments for Measuring Bladder Sensations and Storage Symptoms

Normal LUT sensations during cystometry are (1) first sensation of filling, (2) normal desire to void, and (3) strong desire to void (Wyndaele and De Wachter, 2002). Whether an individual with OAB also experiences normal sensations is not yet established but seems likely. In addition to the urinary tract sensations, cognitive aspects substantially influence voiding behavior (Harvey et al, 2012). Tools for evaluating urgency thus have to address the subjective nature of the symptom, the habit of preemptive voiding at low bladder volumes, and the consequent increased frequency with low levels of urgency, further complicated by adaptive behaviors such as restricting fluid intake. A validation process is necessary to ensure that the tools used are suitable for clinical or research situations (Avery et al, 2004; Abrams et al, 2006).

The urinary sensation scale (Abrams et al, 2005a) is as follows:

1. No urgency: "I felt no need to empty my bladder but did so for other reasons."
 2. Mild urgency: "I could postpone voiding as long as needed without fear of wetting myself."
 3. Moderate urgency: "I could postpone voiding for a short time without fear of wetting myself."
 4. Severe urgency: "I could not postpone voiding but had to rush to the toilet in order not to wet myself."
 5. Urgency incontinence: "I leaked before arriving at the toilet."
- Score 1 on the urinary sensation scale appears in line with a "convenience void," which has been defined as "a void without desire to void" (Honjo et al, 2010).

The urgency percentage scale (Cardozo et al, 2002) includes three possible responses:

1. I am usually not able to hold urine.
2. I am usually able to hold urine until I reach the toilet if I go immediately.

Infection

Pharmaceuticals

Psychological

Excess urine output

Reduced mobility

Stool impaction and other factors

Don't overtreat asymptomatic bacteriuria

3. I am usually able to finish what I am doing before going to the toilet.

The Indevus “Urgency Severity Scale” (Bowden et al, 2003), used in trials of tiroprism, includes four responses:

0. None, no urgency.
1. Mild, awareness of urgency but easily tolerated.
2. Moderate, enough urgency/discomfort that it interferes with usual activities/tasks.
3. Severe, extreme urgency/discomfort that abruptly stops all activities/tasks.

A related strategy used an “urgeometer” (Oliver et al, 2003) in cystometry, which instructs patients to press sequentially a series of five buttons during bladder filling according to their degree of urgency:

0. None.
1. Mild.
2. Moderate.
3. Strong.
4. Desperate.

However, the lower three descriptions on these scales do not explain to patients how urgency is defined; thus the buttons are perhaps inappropriately named because they actually measure intensity of bladder sensation in differing parts of the sensation spectrum. Other measures such as “warning time” (between first sensation of urgency and eventual voiding) also depend on the patients and the clinicians reaching a consensus about the meaning of urgency (Cardozo and Dixon, 2005).

Storage symptoms questionnaires are now available in a modular format, developed to address recommendations made by the International Consultation on Incontinence Questionnaire (ICIQ) group (Abrams et al, 2006). The ICIQ group has adopted several validated tools and has developed new ones where necessary. The King’s Health Questionnaire (Kelleher et al, 1997) and the OAB-q (Coyne et al, 2002) have been adopted as ICIQ modules. A shortened form of the OAB-q has been validated more recently (Coyne et al, 2015).

Urgency assessment is a component of the more generic assessment tools for LUTS and may be of more practical use in clinical practice. For example, the “Patient Perception of Bladder Condition” is a straightforward means to administer and capture the clinical significance that patients attribute to their OAB (Coyne et al, 2008a).

The frequency volume chart (FVC) (Abrams and Klevmark, 1996) remains the principal method for evaluating frequency and nocturia in an objective way. In OAB, the pattern of voided volumes is characteristically erratic. On the FVC, frequency is defined as the number of voids recorded during waking hours including the last void before sleep and the first void after waking and rising in the morning (Abrams et al, 2002). The FVC is valuable for highlighting factors that may hinder successful OAB management, such as nocturia caused by nocturnal polyuria, or other causes of sleep disturbance (Cornu et al, 2012). The maximum voided volume on an FVC can be used as a measure of OAB severity, and it has also been used to estimate severity of DO (Miller et al, 2002). The bladder diary additionally collects information on fluid intake and incontinence episodes. A symptom scale has been evaluated for use in conjunction with a bladder diary validated by the ICIQ group in nonselected populations (Bright et al, 2012, 2014) (Table 76-1).

The Patient Perception of Intensity of Urgency Scale (PPIUS) is a five-point scale designed to rate the level of urinary urgency for each void during completion of a micturition diary (Cartwright et al, 2011).

0. No urgency: I felt no need to empty my bladder but did so for other reasons.
1. Mild urgency: I could postpone voiding for as long as necessary without fear of wetting myself.
2. Moderate urgency: I could postpone voiding for a short while without fear of wetting myself.
3. Severe urgency: I could not postpone voiding but had to rush to the toilet in order not to wet myself.
4. Urge incontinence: I leaked before arriving at the toilet.

TABLE 76-1 Bladder Sensation Scale Used in the International Consultation on Incontinence Questionnaire Bladder Diary

SCALE	DESCRIPTION
0	If you had no sensation of needing to pass urine, but passed urine for “social reasons,” for example, just before going out or because you are unsure where the next toilet is
1	If you had a normal desire to pass urine and no urgency. Urgency is different from normal bladder feelings and is the sudden compelling desire to pass urine that is difficult to defer, or a sudden feeling that you need to pass urine and if you don’t you will have an accident
2	If you had urgency but it passed before you had to visit the toilet
3	If you had urgency and managed to get to the toilet, still with urgency, but did not leak urine

From Bright E, Cotterill N, Drake M, et al. Developing a validated urinary diary: phase 1. *Neurourol Urodyn* 2012;31(5):625–33.

During cystometry, subjects are usually asked to report sensations and are questioned by the investigator about the sensations. These sensations are then mapped onto the following categories: **first sensation of bladder filling** (defined as the first awareness of bladder being filled), **first desire to void** (defined as the desire to pass urine at the next convenient moment but voiding can be delayed if necessary), **strong desire to void** (defined as a persistent desire to void without the fear of leakage), and **urgency** (defined as a sudden compelling desire to void). This approach is consistent when retested after an interval of 1 week (Van Meel and Wyndaele, 2011). A visual analog scale has been described for assessing sensation (Dompeyre et al, 2007). The latter study suggested that the filling sensation is a continuum, which means that it is a single sensation of a desire to void that increases continually during filling.

Increased frequency may be a behavioral response to urgency, as patients attempt to reduce the incidence of severe urgency or incontinence, and this can be assessed with additional interpretations of the measures mentioned previously. The total urgency and frequency score (TUFS) (Chapple et al, 2014) is calculated by adding the PPIUS scores of every void by a patient in the patient’s urinary diary, and dividing this number by the number of days recorded in the diary. The OAB symptom composite score (Zinner et al, 2005) is derived by summation from the Indevus Urgency Severity Scale, but it has not been validated.

Mixed Symptoms Incorporating Urinary Urgency

OAB can coexist with stress urinary incontinence (SUI). Mixed urinary incontinence (MUI) is the **complaint of involuntary leakage associated with urgency and with exertion, effort, sneezing, or coughing** (Abrams et al, 2002). Thus in MUI, both SUI and urgency incontinence (“OAB wet”) are present in the same person. A person with SUI and “OAB dry” does not have MUI; no suitable phrase has yet been standardized for this situation, so such a patient’s mixed symptoms should be categorized descriptively. For example, it may be necessary to state that the patient experiences SUI and urgency but does not have UUI.

The coexistence of urinary and anal incontinence can be referred to as “mixed incontinence,” and it should not be confused with MUI. Figure 76-5 describes the relationships among SUI, MUI, and OAB. In general, MUI is associated with more severe levels of leakage, although the relative contributions of the two types of incontinence can be difficult to clarify. Clarity of communication is necessary to ensure all parties are aware of the specific situation for each individual under consideration.

Figure 76-5. Incontinence may be stress urinary incontinence (SUI), mixed urinary incontinence (MUI), or urgency urinary incontinence (“overactive bladder [OAB] wet”), especially in women. SUI can coexist with “OAB dry,” giving rise to mixed symptoms of stress incontinence and urgency.

Distinguishing Overactive Bladder from Bladder Pain Syndrome

Older standardizations defined urgency as a strong desire to void accompanied by the fear of leakage or the fear of pain (Abrams et al, 1988). However, the urgency of OAB characteristically does not include pain; where pain causing urgency is reported, it is categorized as BPS (see Fig. 76-1) (Abrams et al, 2005b; Hanno et al, 2008). BPS is defined as the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and nighttime frequency, in the absence of proven urinary infection or other obvious pathology. The relationship between urgency and filling sensation is different in OAB and BPS (Fig. 76-6).

Differences that help to distinguish BPS include the painful nature of symptoms, the steady increase in pain with filling, the more consistent voided volumes compared with OAB, and the ability to defer voiding (albeit at the cost of greater pain). In BPS, suprapubic pain is usual and additional perineal (urethral/vaginal/penile) discomfort and/or pain can also occur (FitzGerald et al, 2005); in OAB, urgency is typically felt in the perineum/base of penis or vagina/urethra.

KEY POINTS: OVERACTIVE BLADDER CLINICAL ASSESSMENT

- The minimum requirements to document symptoms and signs of OAB and to exclude other potential causative disorders are a careful history, physical exam, and urinalysis.
- Physicians must consider the possibility of malignancy, neurologic disease, systemic disease, or a significant postvoid residual.
- The most time-efficient and systematic way to evaluate OAB is to use a symptom assessment questionnaire.
- The FVC is the principal method for evaluating frequency and nocturia in an objective way.
- Urodynamics, cystoscopy, and diagnostic renal and bladder ultrasound should not be used in the initial workup of the uncomplicated patient.
- MUI is the complaint of involuntary leakage associated with urgency and with exertion, effort, sneezing, or coughing.
- Unlike OAB, in BPS there is a steady increase in pain with filling, more consistent voided volumes, and the ability to defer voiding.

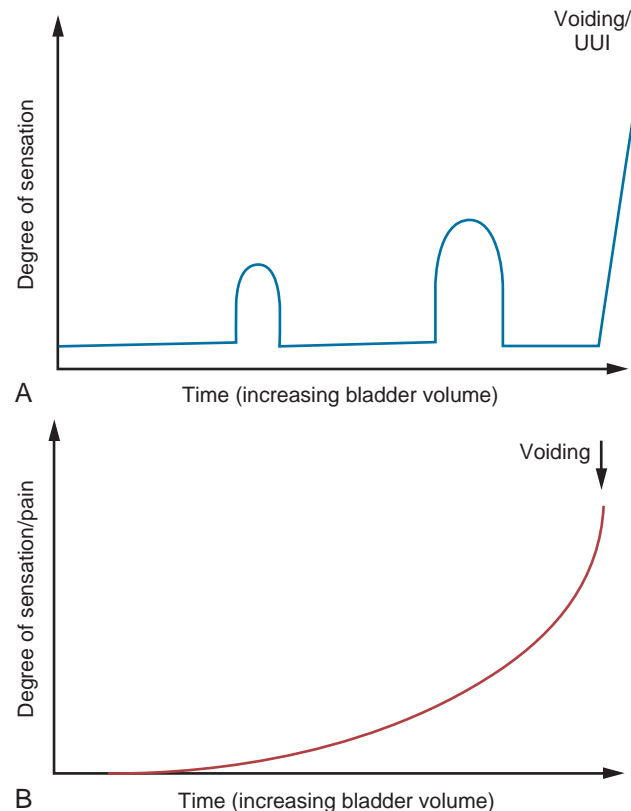

Figure 76-6. The differences in the development of bladder sensation in overactive bladder (OAB) and bladder pain syndrome (BPS). A, In OAB, phasic increases in urgency arise and recede as filling progresses, until severe urgency compels the patient to void or an urgency urinary incontinence (UUI) episode sets in. B, In BPS, pain increases throughout filling, accelerating as filling progresses.

INITIAL TREATMENT OUTLINE

After the diagnosis and baseline severity of OAB have been evaluated, initial treatment can be instigated according to the patient's desire for treatment. It is common practice to use conservative management and oral pharmacotherapy without a urodynamic diagnosis. Because “cure” is not a realistic aspiration, and the condition is generally progressive, appropriate expectations and honest explanation are crucial.

1. After assessment has been performed to exclude conditions requiring treatment and counseling, “no treatment” is an acceptable choice made by some patients and caregivers (Gormley et al, 2012).
2. Lifestyle interventions such as education about the condition, attention to the nature and volume of fluid intake, dietary irritants, and cessation of smoking foster in patients a sense of engagement in their own care.
3. Bladder training and pelvic floor muscle training help patients to reestablish inhibitory control over bladder storage and allow patients to resist and abort urgency episodes.
4. **Drug treatments should be used after conservative approaches have been undertaken**, and these are described in more detail in Chapter 79. If recommending antimuscarinic medication, prescribers should warn the patient about potential side effects including dry mouth, constipation, cognitive effects, visual impairment, and others (Leone Roberti Maggiore et al, 2012). A range of agents and doses is available, and patients should be advised that the idiosyncratic nature of responses means that it may take some adjustment to find an optimum regimen. **Extended release formulations should preferentially be prescribed in favor of short-acting formulations** because of lower rates of dry mouth (Gormley et al, 2012), and if a patient

experiences inadequate symptom control and/or unacceptable adverse drug events with one antimuscarinic medication, then a dose modification or a different antimuscarinic medication may be tried. A β_3 -adrenergic agonist has been introduced for the treatment of OAB, and this provides a new approach to the pharmacotherapy of OAB (Nitti et al, 2013). For men, α_1 -adrenergic blockers are widely used, and they are first-line drug therapy if voiding symptoms are also present (Oelke et al, 2013). For men with LUTS suggestive of OAB pathophysiology, inclusion of an antimuscarinic in first-line therapy is an appropriate option (Drake, 2012). The use of an antimuscarinic in the treatment of a man with BOO and concomitant OAB seems to ameliorate the symptoms and to provide a moderate improvement in quality of life (Athanasopoulos et al, 2011). Incidence of acute urinary retention in men receiving antimuscarinics with or without an α_1 -adrenergic blocker is up to 3% (Kaplan et al, 2011). The availability of various medications for OAB, along with drugs for voiding LUTS in men, provides the potential for combination therapies, which are likely to evolve substantially in the foreseeable future.

In evaluating response, repeat use of the symptom assessment questionnaire is valuable in providing objective markers before and after therapy initiation, as subjective perceptions and recollections of LUTS can be unreliable.

KEY POINTS: INITIAL THERAPY OF OVERACTIVE BLADDER

- After the diagnosis and baseline severity of OAB have been evaluated, initial treatment can be instigated according to the patient's desire for treatment. Repeat use of the symptom assessment questionnaire is more reliable than patient impression in identifying treatment response.
- It is common practice to use conservative management and oral pharmacotherapy without a urodynamic diagnosis.
- Some patients might elect not to receive treatment for OAB.
- First-line treatment is lifestyle intervention, bladder training, and pelvic floor muscle training, and these should precede drug treatments.
- Drug options for both genders include antimuscarinics and a β_3 -adrenergic agonist, and treatment needs to be tailored according to efficacy and adverse effects.
- For men, α_1 -adrenergic antagonists are an additional option.
- Combination therapies may yield additional benefits, for which research is ongoing.

SPECIALIZED EVALUATION AND MANAGEMENT OUTLINE

Where the initial treatment response is deemed inadequate and specialist referral is made, the specialist clinician must review the diagnosis, look for complicating factors, and ensure that suitable initial therapy has been provided. Before urodynamic tests are requested, the potential reasons for "failure" of drug therapy should be explored:

1. Failure to undertake conservative measures before drug prescription.
2. Insufficient duration of prescription.
3. Poor patient compliance.
4. Insufficient dose; individual patients absorb and metabolize drugs differently, so dose titration may be necessary to achieve a therapeutic level. Presence of dry mouth symptoms is a useful rule of thumb for deciding whether dose is adequate.
5. Variability of response; some people appear to find better efficacy with certain agents.
6. Partial response; if urgency and increased daytime frequency have improved, persisting nocturia may reflect either a refractory OAB symptom or the multifactorial nature of nocturia (Gulur et al, 2011).

7. Adverse effects; some patients do exhibit therapeutic improvement in symptoms but tolerate adverse effects poorly.

For each circumstance, altered drug dose, different agent, or combination therapy may achieve sufficient improvement to obviate the need to consider more invasive investigation and treatment. Only when considerable efforts have been made should conservative therapy and antimuscarinic medications be considered unsuccessful.

Urodynamic Testing

The fifth ICI (Abrams et al, 2013) indicates that urodynamic evaluation and imaging should be considered as part of specialist assessment. This applies where conservative and drug therapy fails adequately to manage OAB in a patient who is sufficiently healthy and is considering more invasive therapeutic interventions because of the impact of the symptoms on his or her quality of life. Urethrocystoscopy might be indicated.

The comprehensive symptom score questionnaire, FVC, free flow rate and postvoid residual should be assessed before cystometry and pressure flow studies (see Chapter 73). Whether to discontinue antimuscarinic drugs before urodynamic testing can be argued either way; stopping the drugs provides the best chance of observing DO if present, whereas continuing them allows evaluation of the mechanism underlying residual refractory symptoms.

The primary aim of urodynamic studies is to reproduce the patient's symptoms and to identify additional factors likely to influence management decisions. The two main urodynamic diagnoses associated with OAB are DO (Fig. 76-7) and increased filling sensation. DO presents a variety of patterns on urodynamic traces. The ICS report describes two types:

1. **Phasic DO** is the characteristic pattern seen in most idiopathic DO. It exhibits a characteristic waveform and may or may not lead to incontinence (see Fig. 76-7). It tends to be characterized by contractions of increasing amplitude as the bladder volume increases.
2. **Terminal DO** is a single involuntary detrusor contraction occurring at cystometric capacity, which causes incontinence, often resulting in complete bladder emptying. It is most characteristically seen in the elderly person with "precipitant voiding," such as in elderly patients who have suffered a cerebrovascular accident. Such patients appear to lose awareness of impending micturition and the ability to inhibit what turns out to be a voiding contraction.

Nonphasic changes in detrusor pressure before micturition should be regarded as changes in bladder compliance rather than as DO. Note that some patients with DO are asymptomatic (i.e., they do not experience OAB). Any phasic detrusor contraction during filling constitutes DO, regardless of amplitude (Abrams et al, 2002). Earlier ICS reports (Bates et al, 1980a, 1980b) stated that, to diagnose "detrusor instability" (the old term for DO), the contraction should be at least 15 cm H₂O. However, it was later recognized that involuntary detrusor contractions of lower amplitude could be clinically significant, so the 1988 ICS report (Abrams et al, 1988) was altered accordingly.

It is worth emphasizing that DO may not be present in some patients with OAB, especially in women (Hashim and Abrams, 2006). Figure 76-8 illustrates the relationship between the symptom-based diagnosis of OAB and the urodynamic-based diagnosis of DO. Where DO is absent the patient will usually report increased bladder sensation, that is, an early and persistent desire to void (Abrams et al, 2002). If DO is not seen during filling, the investigator should attempt to use any provocations that the patient says lead to OAB symptoms, such as the sound of running water. Filling rate needs to be considered carefully; a short period of rapid filling can provoke the emergence of DO. However, fast filling can mask DO and cause low compliance, particularly in neurogenic DO.

Urodynamic testing may additionally detect urodynamic stress incontinence (USI) (MUI or mixed storage LUTS). In some patients considered to have OAB based on their symptoms, the ultimate diagnosis turns out to be USI. This might be because contact of

Figure 76-7. Filling cystometry urodynamic trace showing detrusor overactivity incontinence. *Blue*, Bladder pressure (Pves; top). *Red*, Rectal pressure (Pabd). *Purple*, Detrusor pressure (Pdet). *Light brown*, Flow. *Orange*, Filling (VH₂O; bottom). The bladder pressure and detrusor pressure rise substantially from baseline, and between 3 minutes 30 seconds and 4 minutes (top axis) there is incontinence seen in the flow trace that is associated with urgency (Ur).

Figure 76-8. Correlation between the symptom-based diagnosis of overactive bladder (increased daytime frequency [IDF], urgency [U], nocturia [N], and urgency urinary incontinence [UUI]) and the urodynamic diagnosis of detrusor overactivity (DO). The correlation is best for UUI and worst for N.

urine with urethral receptors caused by USI can stimulate urethral receptors, causing an urgency sensation and perhaps a secondary bladder contraction. However, care is needed to ensure that the symptoms are fully reproduced during the test, and that sufficient provocation maneuvers are undertaken to elicit DO. In some individuals, DO can be elicited by asking the patient to cough; this stress-provoked DO (where cough sets off DO, which causes leakage) must not be confused with USI (where the cough causes an immediate leak and no DO is seen).

Pressure flow urodynamics may detect BOO or inefficient bladder emptying. This is crucial, as OAB treatment measures that aim at improving bladder reservoir function may impair voiding, perhaps necessitating intermittent self-catheterization. Some clinicians believe that DO can arise as a consequence of BOO, but the causal relationship is not clear-cut. Prevalence of DO is 60% in men

who have had transurethral resection of the prostate previously (Thomas et al, 2005), despite the fact that they remain unobstructed. Accordingly, relief of BOO does not lead to permanent disappearance of DO. Although symptomatic improvement is seen in many of these men, it is probably less reliable than in men without DO.

Ideally the patient should be seated or standing for filling cystometry, because OAB symptoms are usually experienced when upright. However, where there is severe DO at low volumes, it may be difficult to ascertain if USI is also present. In these patients, a second filling cycle in the supine position generally reduces DO (Al-Hayek et al, 2008), making it easier to detect USI if present.

The urodynamic report must clearly state whether the patients' symptoms were reproduced completely, reproduced in part, or not reproduced to ensure that due caution is exercised in major treatment decisions where there is diagnostic uncertainty. Technical artifacts should be recognized and handled immediately (Hogan et al, 2012). Artifact can easily result if a patient or the equipment is moved during urodynamics.

Ambulatory urodynamics may be considered where conventional cystometry fails to reproduce symptoms. However, DO is then difficult to interpret, as DO might appear in up to 60% of asymptomatic women during ambulatory urodynamics (Heslington and Hilton, 1996).

SPECIALIZED TREATMENT OUTLINE

The fifth ICI (Abrams et al, 2013) has produced a comprehensive review of the spectrum of incontinence management, weighted according to levels of evidence, and providing grades of recommendation (Abrams and Khoury, 2010). The care pathways for OAB and DO in the initial and specialized management algorithms for incontinence in women, men, and the frail elderly are illustrated in Figure 76-4. A more detailed description of the management of OAB is covered elsewhere in this book. In brief, therapy for OAB can be divided into four classes of treatment:

1. Conservative management including weight loss, cessation of smoking, and dietary factors (decreased use of caffeine, decreased fluid intake, decreased alcohol intake, changes in food and drink). Lifestyle interventions include pelvic floor muscle training, to resist and occasionally to terminate overactivity when it arises, and bladder retraining to encourage inhibitory influences on the lower urinary tract.
2. Pharmacotherapy; the antimuscarinics are the mainstay of treatment and can be administered orally or transdermally. A β_3 -adrenergic agonist is now also available. Vanilloid agonists, exemplified by capsaicin and resiniferatoxin, have been used in neurogenic DO; although not currently in use, analogous treatments might become available in the future.
3. Surgical therapy; sacral nerve stimulation, tibial nerve stimulation, intravesical botulinum neurotoxin-A injections, augmentation cystoplasty, and detrusor myectomy.
4. Containment; for intractable OAB, options are appliances, catheters (urethral or suprapubic), urethral closure, and urinary diversion.

Careful assessment of contributory factors and patient capacity is essential to optimize response and to minimize adverse consequences. For example, treatments likely to impair voiding contractility substantially should not be used if intermittent catheterization is not feasible, or indwelling catheterization will not be tolerated.

KEY POINTS: SPECIALIZED EVALUATION AND MANAGEMENT

- The specialist clinician must review the diagnosis, look for complicating factors, and ensure that suitable initial therapy has been provided.
- Urodynamic evaluation should be considered where conservative and drug therapy fails adequately to manage OAB in a patient who is sufficiently healthy and who is considering more invasive therapeutic interventions.
- Comprehensive symptom score questionnaire, FVC, free flow rate, and postvoid residual should be assessed.
- The primary aim of urodynamic studies is to reproduce the patient's symptoms and to identify additional factors likely to influence management decisions.
- The two main urodynamic diagnoses associated with OAB are DO and increased filling sensation. USI and BOO are additional factors of importance in deciding treatment.
- The urodynamic report must state whether the patients' symptoms were reproduced completely, reproduced in part, or not reproduced.
- Therapy options include conservative measures, pharmacotherapy, surgery, and containment. Assessment of contributory factors and patient capacity is essential to optimize response and to minimize adverse consequences of treatment.

Terminology, Definitions, and Symptoms

Epidemiology

Etiopathogenesis

Diagnosis

Management

Conclusions

An impaired ability to empty the bladder is common in both men and women with aging. It may be attributable to increased resistance of the bladder outlet and/or a reduction in the ability to generate an efficient bladder contraction, referred to as *detrusor underactivity* (DUA) by the International Continence Society (ICS), although the symptomatic condition could be labeled the underactive bladder. Increased bladder outlet resistance, far more common in men because of the effect of benign prostatic hyperplasia (BPH) with aging, has been the target of most therapeutic interventions for lower urinary tract symptoms (LUTS) in men. By contrast, DUA mostly lacks any effective treatment other than catheterization (preferably by intermittent self-catheterization [ISC]), when the postvoid residual (PVR) is raised. Despite its common prevalence, which increases with age, in patients with LUTS referred to urologists, the underlying cause and pathophysiologic mechanisms are poorly understood. Recently there has been a resurgence of interest in this poorly understood condition (van Koeveinge et al, 2011; Miyazato et al, 2013; Osman et al, 2014). In this chapter we summarize and discuss the contemporary evidence relating to symptomatology, epidemiology, cause, diagnosis, and management of the underactive bladder.

TERMINOLOGY, DEFINITIONS, AND SYMPTOMS

A confusing multitude of terms are used to describe impaired bladder voiding function, including *impaired detrusor contractility*, *detrusor areflexia*, and *detrusor failure*. The ICS standardization document in 2002 termed the problem DUA defined on the basis of a urodynamic study (UDS) as “a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or failure to achieve complete bladder emptying within a normal time span” (Abrams et al, 2002) (Fig. 77-1A). What constitutes reduced strength, reduced length of contraction, or prolonged emptying is not specified. If no contraction occurs, the term *acocontractile detrusor* is used (see Fig. 77-1B). In clinical practice it is important to distinguish this from an isolated inability to void during a UDS (or “bashful bladder”), which is common and often can be correlated with a history of being unable to void in public restrooms.

Defining DUA in purely urodynamic terms is problematic, because this currently necessitates an invasive test that is neither available nor appropriate in all health care settings. These were some of the reasons why the overactive bladder (OAB) symptom complex was introduced as an adjunct to the urodynamic concepts. Nevertheless the two situations are not entirely analogous, because OAB can be defined by the presence of urinary urgency (albeit variably correlated to detrusor overactivity (DOA)). A **symptom syndrome of underactive bladder** is difficult to define because of the absence of individual symptoms that can be considered pathog-

nomonic of the underlying detrusor abnormality. In particular the symptoms of DUA are diverse and overlap significantly with those seen in OAB and associated with bladder outlet obstruction (BOO). During the voiding phase, patients may experience weak stream, intermittency, hesitancy, and straining. After voiding, some report a feeling of incomplete bladder emptying. In the storage phase, some experience urinary frequency and nocturia whereas others may have a loss of the normal urge to void (the opposite of urinary urgency) and report infrequent voiding. In the presence of a very large PVR, patients may experience incontinence (especially during sleep). One could speculate that the reason for these very different clinical pictures is related to the degree of residual bladder sensation, with patients with very poor sensation typically being infrequent voiders and those with intact sensation voiding frequently in the presence of a raised PVR (Fig. 77-2). A further problem at present relates to the lack of consensus over what represents a clinically significant residual volume in the bladder, with the suggestion being that the threshold is more than 40% of the functional capacity (volume voided + residual).

EPIDEMIOLOGY

Epidemiologic studies have demonstrated that LUTS have a high prevalence in the population, increasing significantly with age. However, the extent to which DUA is a contributing factor is unknown. The Epidemiology of LUTS (EpiLUTS) study, conducted in the United Kingdom, United States, and Sweden, included 30,000 participants over 40 years of age and showed that storage LUTS (occurring at least sometimes) are present in 45.7% of men and 66.8% of women. Voiding LUTS (occurring at least sometimes) were documented in 57.1% of men and 48% of women (Sexton et al, 2009). Postmicturition symptoms occur with a similar prevalence in both men and women. Although it is clearly likely that multiple factors contribute to this clinical picture, it is difficult to establish on a population basis to what extent DUA is a cause of these symptoms because of the lack of a simple noninvasive marker.

In men, voiding LUTS, raised PVR or reduced urinary flow rate, individually or collectively, cannot be used as proxy measures for DUA, because they could be attributed to BOO. Similarly, in women, voiding LUTS such as straining often can occur in the context of frequency and low voided volumes associated with OAB. However, if voiding LUTS occur in association with more objective evidence such as reduced flow rate and raised PVR, underlying DUA becomes more likely as a result of the extremely low incidence of BOO in women (2.7% to 8% of those referred for UDS) (Carr and Webster, 1996).

In the absence of epidemiologic data, clinical studies indicate that in patients with LUTS referred for urodynamic assessment DUA

Figure 77-1. Urodynamic traces. **A**, A 67-year-old man with benign prostatic enlargement and predominant voiding lower urinary tract symptoms. Voiding phase demonstrates low detrusor pressure, prolonged detrusor contraction, and prolonged voiding time. The postvoid residual was 100 mL, and the diagnosis is detrusor underactivity. **B**, A 29-year-old woman with a history of lower back injury and urinary retention managed with intermittent self-catheterization. The diagnosis is acontractile detrusor. Pabd, abdominal pressure; Pdet, detrusor pressure; Pves, intravesical pressure.

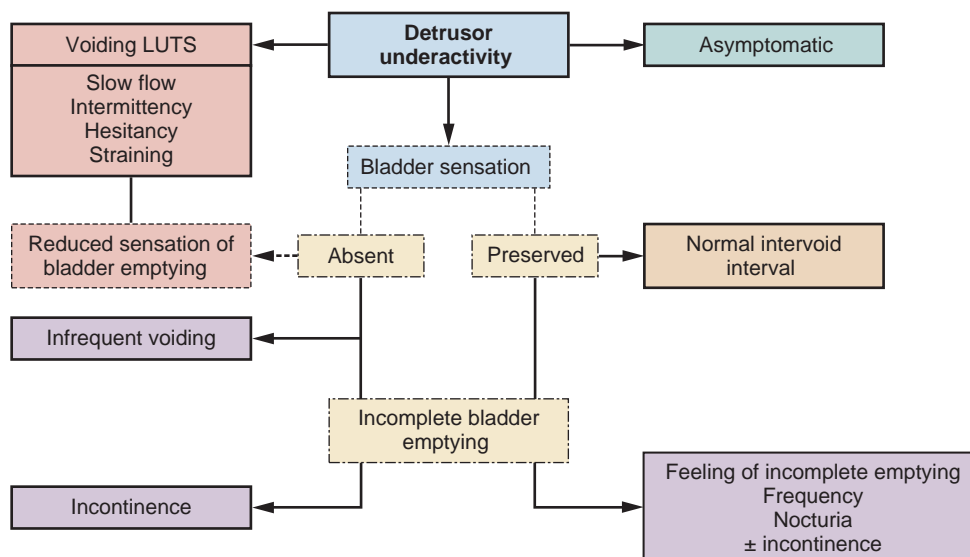

Figure 77-2. Lower urinary tract symptoms (LUTS) in detrusor underactivity (DUA). DUA may manifest with a spectrum of voiding, storage, and postmicturition LUTS or cause no symptoms. Patients with significantly impaired bladder sensation void infrequently and, if bladder emptying is reduced, may have incontinence, typically more pronounced during nighttime (urethral relaxation during sleep). Patients who have preserved bladder sensation can have a normal intervoid interval provided bladder emptying is normal. If bladder emptying is poor, these patients typically experience a sensation of incomplete emptying after voiding, urinary frequency, and nocturia \pm incontinence. This wide variation in symptomatology and its overlap with LUTS/benign prostatic hyperplasia and overactive bladder hampers the development of a reliable symptom-based definition.

TABLE 77-1 Prevalence of Detrusor Underactivity in Clinical Studies

STUDY	POPULATION	SIZE	AGE RANGE OR MEAN AGE (yr)	DIAGNOSTIC CRITERIA	PREVALENCE OF DUA + (% OF ACONTRACTILE DETRUSORS)

DUA, detrusor underactivity; EMG, electromyography; ICS, International Continence Society.

From Osman NI, Chapple CR, Abrams P, et al. Detrusor underactivity and the underactive bladder: a new clinical entity? A review of current terminology, definitions, epidemiology, aetiology, and diagnosis. *Eur Urol* 2014;65:389–98.

is very common, particularly in the older age groups (Table 77-1). DUA is diagnosed in 9% to 28% of males under 50 years of age and 48% in those over 70 years. In females, DUA is present in 12% to 45%, being more common in elderly nursing home residents who often have concomitant DOA, an entity described as detrusor hyperactivity impaired contractility (DHIC) (Resnick et al, 1989). It must be borne in mind that these data cannot be extrapolated to the general population and are limited by the inconsistency in definitions used in these studies, the populations studied, and the post-hoc data interpretation.

One of the largest clinical urodynamic series demonstrated that DUA often coexists with other LUT dysfunctions (LUTDs) in the elderly (Jeong et al, 2012). In their study of 1179 patients older than 65 years, 46.5% of males with DUA also had DOA or BOO and 72.6% of the females with DUA also had DOA or urodynamic stress urinary incontinence (Fig. 77-3). In our opinion this is further support for the case for urodynamic assessment before surgical intervention for LUTS in this group.

Very little is known of the natural history of DUA. In a 10-year study of 69 men with non-neurogenic DUA (with a maximal urinary flow rate [Qmax] of $<$ 15 mL/sec and detrusor pressure [Pdet] at Qmax [Pdet@Qmax] of $<$ 40 cm H₂O) managed conservatively,

there was minimal symptomatic or urodynamic progression (Thomas et al, 2005b). In this cohort, 11 patients underwent transurethral resection of the prostate (TURP), 3 for acute urinary retention and 8 for worsening LUTS (all of whom showed no change in Qmax preoperatively compared to the baseline values).

KEY POINTS: TERMINOLOGY, DEFINITIONS, AND SYMPTOMS, AND EPIDEMIOLOGY

- DUA is a common clinical problem associated with a range of storage, voiding, and postmicturition LUTS.
- The population prevalence of DUA is not known, because of the lack of a noninvasive marker.
- DUA affects 9% to 28% of men under 50 years of age and 48% in those over 70 years undergoing UDS and is more prevalent among the institutionalized elderly.
- In women DUA is found in 12% to 45% undergoing UDS and is more prevalent among the institutionalized elderly.
- DUA commonly coexists with other LUTDs.

Figure 77-3. The overlap between detrusor underactivity (DUA), detrusor overactivity (DOA), and bladder outlet obstruction (BOO) in 1179 patients (632 men and 547 women) older than 65 years in a Korean clinical series of urodynamic studies. DUA was defined as a bladder contractility index less than 100 in men and Qmax 12 mL/sec or less and Pdet@Qmax 10 cm H₂O or less in women. In total, 40.2% of men and 13.3% of women were classified as having DUA. The data suggest a significant overlap between DUA and other urodynamic diagnoses. USUI, urodynamic stress urinary incontinence. (Raw data provided by Dr. Sang Eun Lee. From Jeong SJ, Kim HJ, Lee YJ, et al. Prevalence and clinical features of detrusor underactivity among elderly with lower urinary tract symptoms: a comparison between men and women. *Korean J Urol* 2012;53:342–8.)

ETIOPATHOGENESIS

DUA occurs in both sexes and diverse clinical groups. Several distinct etiologic factors are recognized, such as diabetes mellitus and cauda equina compression. In clinical practice many patients do not have any obvious cause for DUA, neurologic or otherwise, suggesting that DUA may occur secondary to common age-related changes. In particular, an age-related decline in detrusor function with normal aging is likely, although it has not been conclusively demonstrated.

Direct measurement of the contractility of bladder muscle strips from rodents, comparing younger to older animals, has yielded contradictory results that are difficult to extrapolate to humans because of differences in functional innervation. The few studies that used human bladder muscle strips often have failed to demonstrate a decline in contractile responses to electrical stimulation and a variety of agonists (Mark et al, 1992; Yoshida et al, 2001; Fry et al, 2011). Some clinical urodynamic data suggest an age-related reduction in Pdet and flow rate accompanied with an increase in PVR (Pfisterer et al, 2006; Smith et al, 2009; Valentini et al, 2011). Most studies have included symptomatic individuals with probable underlying pathophysiologic abnormalities that could be expected to progress with time. It is to be expected that there would be a more pronounced decline in detrusor contractility in men because of bladder wall changes (increased connective tissue and reduced smooth muscle) occurring as a result of BOO; however, these changes are also seen in women suggesting that they may be partly attributable to normal aging (Lepor et al, 1992; Holm et al, 1995) (Fig. 77-4A to C).

The mechanisms by which different causes result in DUA can be classified as (1) myogenic, affecting the cellular functions of detrusor myocytes or the surrounding extracellular matrix; or (2) neurogenic, affecting the afferent pathways, efferent pathways, or brain circuits involved in the micturition reflex. (These mechanisms and the probable major etiologic factors are summarized in Fig. 77-5.)

Myogenic Factors

Processes that alter the normal structure and function of the detrusor muscle extracellular matrix may result in diminution of transmitted contractile force. The intrinsic ability of detrusor muscle cells to generate contractile activity may be compromised by dysfunction of cellular mechanisms (e.g., ion storage/exchange, excitation-contraction coupling, calcium storage, energy generation) such that even in the presence of normal extrinsic neuronal activity, a reduced contraction may occur (Brierly et al, 2003).

Morphologic changes have been reported to occur in the detrusor with normal aging and disease. Elbadawi and colleagues (1993a, 1993b, 1993c) proposed that distinct ultrastructural patterns observed by electron microscopy characterized the normally contractile aging detrusor and different bladder dysfunctions, including DUA. Although the applicability of this classification system is disputed, other groups have noted similar findings (Hindley et al, 2002; Brierly et al, 2003). This degeneration pattern, which consists of widespread disrupted detrusor myocytes and axonal degeneration, has been associated with DUA (Elbadawi et al, 1993a). Whether detrusor myocyte disruption is the cause of DUA or a consequence of a pathologic insult is not clear (see Fig. 77-4D to E).

Neurogenic Factors

Brain Circuits

The central neural control mechanism governing micturition involves key processes including perception and integration of storage and voiding that, if disturbed, may result in DUA (Suskind and Smith, 2009). The micturition reflex is facilitated by the spino-bulbo-spinal pathway passing through the sacral parasympathetic nucleus and the pontine micturition center (PMC). The PMC receives input from higher centers in the cerebral cortex and in particular the limbic system. Many insights have been gained from functional neuroimaging studies in animals (de Groat et al, 1998; Sugaya et al, 2003, 2005). Certain populations of PMC neurons ("direct neurons"), appear to become activated immediately before and during reflex bladder contractions, whereas outside these periods they are completely inactive. A large number of these neurons pass to the lumbosacral spinal cord, suggesting a role in the micturition reflex. Human functional neuroimaging suggests similar areas of the brainstem and cortex are implicated—the insula, hypothalamus, periaqueductal gray, and PMC (Blok et al, 1997). Any lesion affecting these regions could in theory result in DUA, albeit a clinical correlation between the site of a neurologic lesion and the urodynamic finding is not always apparent in all diseases (Kim et al, 1998).

Bladder Efferent Pathways

Interruption or impairment of efferent signaling in the sacral cord, sacral roots, and pelvic nerves may manifest as absent or reduced detrusor contraction. There is evidence to suggest that a reduction in autonomic innervation occurs in human bladders as a consequence of normal aging (Gilpin et al, 1986). A range of diseases and injuries can result in disturbance of efferent signaling (discussed later in this section).

Bladder and Urethral Afferent Pathways

Intact bladder sensation is critical to the functioning of the efferent limb of the micturition reflex. Bladder afferents monitor both volumes during bladder filling in the storage phase of the micturition cycle and the magnitude of detrusor contractions during the voiding phase. Urethral afferents have an important role in the perception of both flow through the urethra and detrusor contraction (Feber et al, 1998; Bump, 2000). An impairment in afferent function (from bladder or urethra) is likely to reduce or prematurely end the micturition reflex, leading to impairment or

Bladder outlet obstruction and normative aging are probable rather than definite factors. BPH, benign prostatic hyperplasia; PAG, periaqueductal gray; PMC, pontine micturition center.

loss of voiding efficiency (Suskind and Smith, 2009). There is evidence that normal aging is associated with a decline in sensory function in the LUT. In support of this, an age-related increase in the thresholds for reaching bladder capacity was observed in women (Pfisterer et al, 2006, 2007) and functional magnetic resonance imaging in asymptomatic older people has shown a reduced response to bladder filling in the insula (the region that maps visceral sensation).

Given that both tissue changes and a decline in sensory function appear to occur with aging, it is likely that both factors contribute to DUA in the elderly. An interesting hypothesis that integrates both aspects has been proposed (Smith, 2010). It is based on the concept that afferent outflow is a function of bladder wall stress and suggests that increased connective tissue deposition and smooth muscle disruption results in a loss of bladder elasticity that leads to changes in the normal passive compliance curve. There would also be impairment of normal sensory innervations resulting from connective tissue infiltration into the bladder wall. Conceptually the bladder progressively loses the property of receptive relaxation and becomes more akin to a stiff balloon. Such a stiff-walled bladder will exhibit a precipitous rise in wall stress with physiologic filling. Clinically this would be manifested by delayed bladder sensation and soon after this the sensation of urgency as the functional bladder capacity is reached. After a small volume of urine is passed, wall stress is dramatically reduced, with a reduction in afferent stimulation resulting in premature termination of the detrusor contraction before the bladder is emptied and an increased PVR. This is a potential explanation for the finding of DHIC, which has been described to occur with aging (Resnick and Yalla, 1987).

Specific Etiologic Factors

See Box 77-1.

Bladder Outlet Obstruction

DUA also may occur as consequence of a series of changes in the detrusor induced by the increased work requirements to overcome bladder outlet obstruction (BOO). In rodent models of partial BOO, the sequence of events leading to DUA is well described and has been separated into three stages. Initially a surgically created BOO (e.g., ring or ligature) increases bladder outlet resistance and results in bladder distention. The detrusor muscle then undergoes compensatory hypertrophy and hyperplasia, with bladder weight increasing sharply over the next few weeks before stabilizing. During this time tissue blood supply also increases. The contractile function at this point is almost normal, and the bladder is said to have entered the compensated stage—in which mass and function remain relatively stable. After a period of variable length, detrusor contractile function declines and bladder emptying is impaired, marking the decompensation phase (Levin et al, 1992, Saito et al, 1997). This is characterized by reduced response to electrical stimulation and agonists and replacement of bladder muscle with connective tissue (fibrosis). Typically, if the obstruction is not relieved before the stage of decompensation and connective tissue deposition, permanent contractile dysfunction ensues. In such an obstructed bladder, laser Doppler estimation of blood flow has demonstrated this to be decreased, further contributing to the bladder wall dysfunction by a direct effect on both neural and muscular dysfunction (Greenland and Brading, 1996). Other work has demonstrated that there is denervation of the bladder as a consequence of BOO in both humans and an animal model (Harrison et al, 1987; Sibley, 1987).

Clearly the hypothesis for the sequential changes observed in animals centers on ischemic/reperfusion injury and pathologic connective tissue infiltration consequent on increased intravesical pressure being necessary to overcome outlet resistance. This results in increased bladder wall tension during contraction (the law of

Laplace). This leads to compression of bladder wall vessels, tissue ischemia, and hypoxia. Cycles of ischemia and reperfusion during the micturition cycle (as the bladder empties and then fills) lead to generation of reactive oxygen species (Erdem et al, 2005) and release of free intracellular calcium. These factors cause activation of proteases, phospholipases, and membrane lipid peroxidation, which damages cellular and subcellular membranes, including nerve cells, synaptic membranes, mitochondria, and sarcoplasmic reticulum. The outcome of these processes is impaired cellular function and denervation, leading to decompensation of detrusor function (Schroder et al, 2001).

Relating the insights from this work to humans is problematic, because the animals studied are usually immature and often female; the obstruction is acute and certainly not representative of the clinical scenario. Indeed, the sequential changes that have been described, with consistency, do not correlate with the diverse outcomes men with BOO experience clinically. In addition, this sequence of events is not seen in patients presenting with a urethral stricture and does not explain the genesis of the similar bladder dysfunction seen clinically in female patients.

A longitudinal study has demonstrated that prolonged BOO commonly does not necessarily result in clinical decompensation. In a cohort of 170 men with BOO followed for a mean of 13.9 years, no significant deterioration was found in urodynamic parameters (no change in p_{det}@Q_{max} (detrusor pressure at maximum flow) and a reduction in Q_{max} (maximum flow rate) of only 1 mL/sec) and only 17% required any form of intervention (Thomas et al, 2005a). Of men who decompensate their bladders acutely (i.e., develop acute urinary retention), most have preserved detrusor function. Even among men with chronic retention there are some who have preserved contractility and typically poor compliance and upper renal tract changes (high-pressure chronic retention) (George et al, 1983, Djavan et al, 1997). The pathophysiologic explanation for these divergent clinical outcomes remains unknown.

Some aspects of the pathophysiology relating to BOO remain unclear. Animal models do not predict or explain what is seen in the clinical setting. It is likely that the clinical picture in any individual patient is multifactorial and thus unlikely to be explained by any single hypothesis.

Diabetes Mellitus

Diabetes mellitus may impair detrusor function through a combination of myogenic and neurogenic mechanisms. Diabetes-induced bladder dysfunction (DBD), classically termed *diabetic cystopathy*, results in a reduction in emptying efficiency in a time-dependent fashion during the course of the disease (Lee et al, 2004; Lifford et al, 2005). This is traditionally attributed to an autonomic neuropathy occurring as a result of axonal degeneration and segmental demyelination resulting in diminished bladder sensation (Hill et al, 2008). The mechanisms underlying this process are thought to occur as consequences of hyperglycemia. These include activation of the polyol pathway, increases in the generation of free radicals, activation of protein kinase C, and formation of advanced glycated end products (Daneshgari et al, 2009; Miyazato et al, 2013). It has been suggested that a reduction in nerve growth factor (essential for maintaining normal sympathetic and sensory nerve function) is also implicated in DBD. In support of this, studies in streptozotocin-induced diabetes mellitus in rats have shown reduced levels of nerve growth factor in the dorsal root ganglia associated with increased PVR and bladder capacity (Hellweg et al, 1994; Sasaki et al, 2002).

DBD also may result from detrusor myocyte dysfunction occurring as a result of alterations in intercellular connections and excitability, intracellular signaling, receptor density, and distribution. These mechanisms are poorly understood; most insights are derived from animal studies, which have demonstrated both increases and reductions in bladder contractility. Daneshgari and colleagues

(2009) suggested this may be explained by time-dependent changes occurring in the bladder wall, the DBD temporal theory. This theory postulates that initially osmotic diuresis induced by hyperglycemia causes bladder wall stretching, which with increased intravesical pressure results in compensatory bladder hypertrophy. This stage would correspond clinically to storage symptoms early in the disease time course. It is suggested that as the disease progresses, accumulation of toxic products of oxidative stress results in bladder decompensation, clinically manifested as poor bladder sensation and impaired voiding function with associated LUTS.

Neurologic Disease or Injury

A range of neurologic diseases or injuries affecting the brain, spinal cord, or peripheral nerves can lead to DUA (see Box 77-1). Although neurogenic DOA is the most common chronic urologic sequela of cerebrovascular accident, in the acute phase approximately half of patients develop urinary retention (attributed to “cerebral shock”); 75% of these have acontractile detrusors (Burney et al, 1996). Similarly in Parkinson disease DUA is far less common than DOA, occurring in less than 20% of cases (Araki et al, 2000).

Anticholinergic parkinsonian medication may be an important contributor; in a study in which these were withdrawn before urodynamic assessment, DUA was not demonstrated in any patient (Stocchi et al, 1997). Multisystem atrophy, otherwise known as Shy-Drager syndrome, is a condition often confused with Parkinson disease, in which 52% to 95% of patients demonstrate DUA on UDS (Bloch et al, 2010; Yamamoto et al, 2014) as a result of atrophy of efferent parasympathetic nerves, and clinically the majority of these patients develop urinary retention. DUA occurs in 20% of patients with multiple sclerosis (Litwiller et al, 1999), particularly when plaques affect the lumbosacral cord.

Injury at the level of lumbosacral spinal cord, the cauda equina, and sacral and pelvic nerves can occur as a result of trauma or a prolapsed intervertebral disk and also commonly results in DUA related to cauda equina syndrome. In particular, radical pelvic surgery can lead to injury to the pelvic plexus (located near the

anterolateral wall of the lower rectum) or postganglionic fibers that traverse the lateral wall of the upper vagina.

A systematic review found that the overall incidence of LUTD after radical hysterectomy was 72% (Plotti et al, 2011). Although high incidences were reported in older series of patients undergoing rectal cancer surgery, more recently lower rates have been reported (<5%) (Maurer et al, 2001), which can be attributed to the adoption of nerve-sparing techniques. The true incidence of DUA in this context is difficult to define because of the lack of studies correlating preoperative and postoperative urodynamic findings. Nevertheless many patients appear to recover bladder function by 1 year after surgery. In support of this, a study of feline pelvic plexus extirpation suggests this may be due to restitution of intrinsic cholinergic nerves and muscle cell regeneration after an initial injury-related degeneration (Elbadawi, 1988).

In neurologic disorders associated with infective causes, DUA can be either entirely reversible, such as in Guillain-Barré syndrome and herpes zoster (shingles), or permanent, as seen with progressive problems such as acquired immunodeficiency syndrome or neurosyphilis (tabes dorsalis) as was common in the preantibiotic era.

DIAGNOSIS

The only accepted modality for clinically estimating detrusor voiding function is an invasive UDS; however, there are currently no universally agreed criteria for diagnosing DUA. Current methods of estimating detrusor voiding function almost exclusively focus on detrusor contraction strength (Table 77-2), neglecting other potentially important aspects such as the speed and sustainability of a detrusor contraction.

Detrusor Contraction Strength

A detrusor contraction generates both pressure and flow (Griffiths, 2003); thus many authors have used two parameters to diagnose DUA: Qmax and Pdet@Qmax. Reductions in both are considered

TABLE 77-2 Summary of Diagnostic Methods and Criteria

TYPE	METHOD	ADVANTAGES	LIMITATIONS
Mathematical calculations	Watts factor	1. Measure of bladder power 2. Minimally dependent on volume of urine 3. Not affected by presence of BOO	1. Lengthy and complex calculation 2. No validated thresholds 3. Does not measure sustainability of contraction
	Detrusor shortening velocity	1. May identify early-stage DUA	
Indices	Detrusor contraction coefficient (DECO)	1. Simple to use 2. Measurement easy to obtain	1. Does not measure sustainability of contraction
	Bladder contractility index (BCI)	3. Estimation of isovolumetric contraction	2. May not be applicable to other groups
Occlusion testing	Voluntary stop test	1. Real-time indication of isovolumetric contraction strength	1. Uncomfortable or painful for patients
	Mechanical stop test Continuous occlusion	2. No calculations	2. Impractical 3. No information on sustainability of contraction in (in continuous occlusion) 4. May underestimate isovolumetric pressure (stop test) 5. Unusable in some patient groups
Ranges of urodynamic measurements	Pdet@Qmax (e.g., <40) Qmax (e.g., <15)	1. Simple to use	1. No widely accepted “normal” ranges 2. Underestimate contraction strength 3. Does not conceptually consider coexistence of BOO and DUA

BOO, bladder outlet obstruction; DUA, detrusor underactivity; Pdet, detrusor pressure.

From Osman NI, Chapple CR, Abrams P, et al. Detrusor underactivity and the underactive bladder: a new clinical entity? A review of current terminology, definitions, epidemiology, aetiology, and diagnosis. *Eur Urol* 2014;65:389–98.

KEY POINTS: EITOPATHOGENESIS

- The etiopathogenesis of DUA is incompletely understood; a diverse range of factors and pathophysiologic mechanisms are likely to be implicated.
- Confirmed etiologic factors include neurologic injury/disease and diabetes mellitus; BOO and normal aging are probable rather than definite contributory factors.
- These factors may cause DUA by impairing or disrupting processes that are essential for the generation of an efficient voiding contraction.
- The pathophysiologic mechanisms can be classified as follows:
 - Myogenic: Affecting detrusor myocytes or their surrounding extracellular matrix
 - Neurogenic: Affecting the central neural control mechanisms governing the voiding reflex by an action on either afferent or efferent nerves

to be below the lower limits of the normal ranges for the particular patient group. For men these ranges were derived from series of patients undergoing bladder outlet surgery (Abrams and Griffiths, 1979; Schäfer et al, 1989). In healthy men and women these ranges are less well characterized (Schmidt et al, 2002; Pfisterer et al, 2006; Rosario et al, 2008).

There are two limitations with this approach. First, it is likely to underestimate the contraction strength because of bladder outlet relation (BOR), the normal inverse relationship between Pdet and urine flow (Griffiths, 1973). The BOR is an adaptation of the Hill equation for actively contracting muscle and can be summarized as during voiding when flow is low the pressure is high and vice versa. On this basis the Pdet@Qmax actually represents the point of least pressure. Second, the variability in bladder outlet resistance that also can affect flow rate is not considered. The clinical implications of this are that when Pdet is low, a low Qmax also can be attributed to increased outlet resistance (e.g., BOO caused by BPH) or alternatively a normal Qmax can result from reduced outlet resistance (e.g., postprostatectomy incontinence).

To more accurately assess contraction strength, methods that estimate isovolumetric pressure were developed. These are based either on post-hoc mathematical calculations or volitional or mechanical interruption to the flow of urine during UDS (Griffiths, 2004). Many of these are complicated, time-consuming, or impractical limiting their use in clinical practice.

The Watts factor (WF) is an estimate of the power per unit area of bladder surface that is generated by the detrusor, corrected for the finite power required for either isometric contraction or for shortening against no load. It is calculated by the formula: $WF = [(P_{det} + a)(V_{det} + b) - ab] / 2\pi$ where V_{det} is detrusor shortening velocity and a and b are fixed constants ($a = 25$ cm H₂O, $b = 6$ mm/sec), derived from experimental and clinical data (Griffiths, 1991). Throughout micturition the WF varies because of the variation in Pdet and Vdet; the points proposed to best represent detrusor contraction strength is the point at which the WF peaks, the maximal WF (WFmax). The major advantages of the WF are that it minimally depends on volume (Griffiths, 1991) and that it is not affected by increased outlet resistance (Lecamwasam et al, 1998). However, as of yet there are no validated cutoffs for the normal range, but based on expert opinion a WFmax of 7 W/m² was deemed to represent the threshold for reduced contractility (van Koeveeringe et al, 2011), although some authors use a value of 10 W/m² (Mitsui et al, 2012). Ultimately the WF found little use in everyday clinical practice because of the complexity of the calculation and as with all current measures it does not consider the sustainability of a contraction.

Schäfer (1995) proposed an alternative method of estimating isometric contraction strength that is based on superimposing the BOR on his pressure-flow nomogram. The BOR is simplified to a straight line and “projected” back to the y-axis (Pdet) from the point representing Pdet@Qmax to obtain the isovolumetric

Figure 77-6. Method of determining the projected isovolumetric pressure. The point marking the detrusor pressure (Pdet) @Qmax is plotted on Schäfer's contractility nomogram and is projected back to the y-axis. In this case the pressure is 130 cm H₂O, which is in the normal contractility range.

pressure (Fig. 77-6). This projected isovolumetric pressure (PIP) can be calculated by the formula $PIP = P_{det}@Q_{max} + KQ_{max}$, where K is a fixed constant representing the slope of the BOR (Schäfer, 1995). The value of K depends on the specific population studied. In men with BPH it is taken as 5 cm H₂O/mL/sec, whereas in older women 1 cm H₂O/mL/sec was found to be more accurate (Griffiths, 2004).

Based on this the suggested formula for use in men in clinical practice is as follows:

$$PIP = P_{det}@Q_{max} + 5 Q_{max}$$

A PIP greater than 150 represents strong contractility, 100 to 150 normal contractility, 50 to 100 weak contractility, and less than 50 very weak contractility. The corresponding BORs at these cutoffs were plotted on the Schäfer pressure-flow nomogram, to give subdivisions for contractility (see Fig. 77-6).

Although there are two other reported variations of PIP, all three are essentially the same. The detrusor coefficient is the PIP divided by 100, where a value less than 1 signifies weak contraction.

$$PIP = P_{det}@Q_{max} + 5 Q_{max} / 100$$

The bladder contractility index, described by Abrams, is calculated using the same formula as PIP and includes three groupings (strong > 150, normal 100 to 150, and weak < 100) (Abrams, 1999). Evidently all these methods are fairly easy and quick to calculate but tend to overestimate PIP, because such adjustments need to be made for use in different populations. Although test-retest reliability is thought to be acceptable, it is less consistent than measures that directly record isovolumetric pressures (Tan et al, 2003).

Isovolumetric pressure can be measured directly by mechanically obstructing the flow of urine (Sullivan, 2007). This can be achieved through either (1) a stop test, interruption of urine flow after it has begun, or (2) continuous occlusion test, in which the urine outflow is blocked before and during the course of the voiding contraction.

There are two types of stop test: a voluntary stop test, in which the patient voluntarily contracts the urethral sphincter, and a mechanical stop test, in which the bladder outflow is occluded by the investigator (e.g., by tugging a catheter balloon against the bladder neck). These techniques correlate well with each other in both sexes

(Tan et al, 2003), but the voluntary stop test tends to produce a lower value for isovolumetric pressure by approximately 20 cm H₂O. This is probably explained by the reflex detrusor inhibition induced by urethral sphincter contraction (Sullivan et al, 1995). The voluntary stop test is difficult and sometimes impossible to conduct in patients with urethral sphincter weakness. The continuous occlusion testing has greater test-retest reliability and allows assessment of sustainability of contraction, although the consequence is that a representative flow measurement during that particular contraction is not obtained. Although it correlates well with the ability of bladder to empty (Sullivan and Yalla, 1996), continuous occlusion is potentially painful and has found little applicability outside of a research setting.

Detrusor Contraction Speed

A bladder that contracts more slowly could in theory result in clinical symptoms, although this is not part of the ICS definition. A reduction in detrusor shortening velocity (calculated by the formula $V_{det} = Q/2[3/(V + V_t)/4\pi]^{0.66}$, where Q represents the flow rate [milliliters per seconds], V represents bladder volume [in milliliters], and V_t represents the volume of noncontracting bladder wall tissue) was found to precede reduction in WF in series of longitudinal studies in both males (Cucchi et al, 2007, 2010) and females (Cucchi et al, 2008).

Detrusor Contraction Duration

A detrusor contraction of reduced duration is suggested by the ICS as part of the definition of DUA (Abrams et al, 2002); however, the limits of a normal voiding detrusor contraction are not defined. There are only a few studies that assess contraction duration as a urodynamic parameter. In a study of men with BPH, unobstructed patients with poor contractility actually had significantly longer contraction durations than those with no obstruction and normal contractility (Ameda et al, 1998). It is likely that the contraction duration reflects the underlying pathophysiologic mechanisms—for example, an early termination of the micturition reflex could presumably lead to a shorter duration. A standardized method for measuring duration of the detrusor contraction is needed before any conclusions can be reached.

Bladder Sensation

An assessment of bladder sensation is clearly relevant to the evaluation of DUA because the afferent nerves play such a central role in the initiation and maintenance of a detrusor contraction. This is most commonly undertaken using the patient's perceptions of bladder filling (first sensation, first desire, strong desire, and capacity).

Thresholds in normal individuals are available (Wyndaele, 1998), although this method can be criticized because patients may report bladder sensation even when the bladder is not being filled (Erdem et al, 2004; De Wachter et al, 2008); as with any subjective measure, there is substantial individual variation because of the circumstances of a UDS and the anxiety level of the study subject. Testing sensory responses to the passage of electrical current through the bladder wall (current perception threshold testing) may provide a more objective measure but is clearly rather an invasive approach and is as yet an unvalidated research technique.

Ambulatory Urodynamics

Patients often fail to void during UDS because of anxiety or a so-called bashful bladder. It is thought this arises as a result of poor pelvic floor relaxation and reflex detrusor inhibition. Alternatively the patient may have true DUA or acontractile detrusor. A careful history is usually sufficient to differentiate the two situations. Where doubt exists, ambulatory UDS may be useful (Rosario et al, 2000). van Koeveering and colleagues (2010) demonstrated that 84% of patients who failed to generate a detrusor contraction during

standard UDS had evidence of demonstrable contraction during an ambulatory study.

KEY POINTS: DIAGNOSIS

- There is no published consensus on the diagnostic criteria for DUA.
- Most available criteria focus on the strength of contraction as determined by the Pdet during UDS.
- Several indices and formulas to estimate isometric detrusor strength are available, most of which are unvalidated and are not applicable to all patient groups.
- Urodynamic stop and occlusion tests are more reliable but may be painful and impractical.
- The significance of other aspects of detrusor contraction such as speed and duration is unclear.

MANAGEMENT

The goals of managing the patient with DUA are to improve symptoms and quality of life and reduce the risk for the complications of impaired bladder emptying. These include urinary tract infections (UTIs), bladder stones, ureteric reflux leading to back-pressure on the upper urinary tract, and skin damage from urinary overflow incontinence associated with chronic retention. There is a profound lack of effective treatments to improve detrusor function and thereby facilitate bladder emptying. Thus management commonly entails bladder drainage techniques (e.g., catheterization) or therapies aimed at reducing bladder outlet resistance, for example, by relaxing the external urethral sphincter mechanism. The clinical approach and therapies that are available in contemporary clinical practice as well as potential experimental approaches are reviewed in the next sections (Fig. 77-7).

Initial Assessment

The assessment of patients with symptoms suggestive of DUA entails routine urologic evaluation (bladder diary, digital rectal examination, urinalysis, uroflowmetry, PVR estimation using ultrasound) and neurologic assessment (sacral dermatomes anal tone, the bulbocavernosus reflex, lower limb reflexes). Neurologic deficits require further specialist evaluation; magnetic resonance imaging of the spine is commonly performed in particular to assess the lumbar spinal cord and cauda equina. A careful drug history should be taken to identify medications that impair bladder contractility (agents with anticholinergic or opioid effects) (see Box 77-1) or that increase outlet resistance (e.g., α -adrenoreceptor agonists). Fecal impaction/constipation may contribute to poor bladder emptying by a direct obstructive effect, and, if identified, its treatment may facilitate improved bladder emptying (Charach et al, 2001).

Conservative Management

Behavioral interventions in patients with DUA aim to reduce the symptoms and complications of incomplete bladder emptying. Scheduled voiding can be instituted to increase the frequency of voids in patients with sensory impairment. Double voiding to improve bladder emptying may help reduce bothersome frequency, and patients often use this strategy before seeking treatment. Bladder expression techniques such as Valsalva voiding or the Credé maneuver are used in only very specific neurogenic situations (i.e., DUA with incompetent sphincter) and are otherwise not recommended because of the risk for generating high vesical pressure, causing vesicoureter reflux or reflux into the prostate and seminal vesicles.

Pelvic floor physiotherapy and biofeedback have been used to successfully treat children and adults with dysfunctional

	In routine clinical use	Experimental	Not recommended
Drainage	Time voiding/double voiding		Compression
	Catheterization		Reflex voiding
	Urine diversion		Valsalva voiding

voiding (de Jong et al, 2007; Minardi et al, 2010). In this group, poor relaxation of the pelvic floor muscles and the external urethral sphincter mechanism may obstruct urine flow and cause reflex inhibition of detrusor contraction. In a study by van Koeveeringe and colleagues (2010), 24% of patients with acontractile detrusors on conventional UDS who subsequently demonstrated contractility on ambulatory studies were successfully treated with physiotherapy.

ISC is the preferred method of establishing bladder drainage in patients with problematic high PVR. Provided cognition and dexterity are adequate, this method is safe and effective, with lower infection rates than with indwelling catheters. Specific problems include urethral bleeding (one third of patients) (Webb et al, 1990) and production of false passages. Additionally, the technique may be time-consuming and socially restricting; some patients may be unable to overcome the psychological barriers such as a fear of inflicting harm or infection (Mangnall, 2012). An indwelling urethral catheter is best avoided in the long term, and in this context a suprapubic catheter is the best long-term option in patients unwilling or unable to perform ISC.

Pharmacotherapies

Parasympathomimetics for Underactive Bladder

Acetylcholine is the principal neurotransmitter mediating bladder contraction, acting on muscarinic (M_3) receptors. Parasympathomimetic agents, including direct muscarinic receptor agonists or anticholinesterases, have been used with the aim of increasing bladder contractility. Bethanechol and carbachol, the most common compounds studied, are quaternary amines that are selective for the muscarinic receptor but not receptor subtype selective. In mechanistic terms these compounds are more likely to be effective if the problem is reduced or absent contractile stimulus (e.g., reduced efferent input, impaired acetylcholine release from parasympathetic nerves, increased acetylcholine breakdown). Anti-

cholinesterases (e.g., distigmine) would require the presence of at least some endogenous acetylcholine, to amplify its effect. Conversely if the underlying cause is reduced tissue responsiveness to stimulation (e.g., detrusor muscle cell dysfunction, bladder wall fibrosis), parasympathomimetics are less likely to benefit. Similarly, if the problem is loss of the detrusor muscle, no pharmacotherapy is likely to be effective.

The efficacy of parasympathomimetics has been assessed in a small group of heterogeneous studies, mainly for the prevention and treatment of postoperative urinary retention. A systematic review of this literature (Barendrecht et al, 2007) found only 4 of 10 randomized clinical trials included (two of the four in patients with DUA) showed a significant benefit over placebo. However, all of these studies could be considered to be underpowered. Bethanechol was used in all four (dose of 10 to 50 mg up to four times daily). A further three studies failed to show any advantage with use of this agent. One study found that distigmine (5 mg) actually increased PVR compared to placebo. It was concluded there is little, if any, benefit in using parasympathomimetics.

When bethanechol is given to neurologically normal individuals it causes a rise in bladder wall stiffness and sensory perception (De Wachter and Wyndaele, 2001). De Wachter and associates (2003) also noted that women with DUA responding to bethanechol demonstrated significant reductions in bladder sensory thresholds. Hence, intact sensory pathways may be a prerequisite for improvement in voiding with muscarinic agonists, which may explain their lack of efficacy in unselected groups. Alternatively it could be that the doses used are simply too low because of the concern with side effects. Parasympathomimetics are associated with significant dose-dependent systemic side effects, including nausea, bronchospasm, abdominal cramping, diarrhea, increased salivation, flushing, and visual disturbance. A rare but potentially lethal side effect is severe cardiac depression resulting in cardiac arrest. In contemporary practice, parasympathomimetic agents are generally avoided because of their questionable efficacy and potentially serious side effects.

α-Adrenoreceptor Antagonists

α-Adrenoreceptor antagonists have been used to reduce bladder outlet resistance in children and adults with both neurogenic bladder and dysfunctional voiding. [Chang and associates \(2008\)](#) studied the use of tamsulosin (0.2 mg) in 52 women with DUA (Pdet@Qmax <10 cm H₂O), finding 38.5% had a greater than 50% improvement in voiding LUTS, 53.8% had a greater than 30% improvement in Qmax, and 32.7% were judged to have had a good therapeutic response ([Chang et al, 2008](#)). Combination therapy with an α-adrenoreceptor antagonist and a parasympathomimetic has long been considered a therapeutic possibility ([Khanna and Gonick, 1975](#)). In a prospective single-blind randomized study of 119 patients with DUA, urapidil alone did not result in a reduction in Qmax in either sex and led to a reduction in PVR in women only ([Yamanishi et al, 2004](#)). By contrast a combined regimen of urapidil (60 mg) with either bethanechol (60 mg) or distigmine (15 mg) led to significantly improved flow rates (by 2.66 mL/sec in women, $P < .01$, and 4.33 mL/sec in men, $P < .05$) and significantly reduced PVR in women (by 54.1 mL/sec, $P < .01$) ([Yamanishi et al, 2004](#)).

Prostanoids

Prostanoids are a subclass of signaling molecules that may be implicated in the micturition reflex. The efficacy of prostanoids in treating DUA is not clear. Most clinical studies have evaluated the effect of intravesical prostaglandin (PG) instillation in the prevention of postoperative urinary retention.

There are five principal endogenous prostanoids (PGE₂, PGF_{2α}, PGI₂, PGD₂, and thromboxane A) that are all synthesized in the bladder wall and released into the general circulation when the bladder is stretched ([Maggi, 1992](#); [Rahnama'i et al, 2012](#)). Detrusor contraction in response to acetylcholine and adenosine triphosphate stimulation is enhanced by prostanoid production. Conversely, nonsteroidal anti-inflammatory agents (inhibitors of prostanoid synthesis) cause a loss of tone in the isolated bladder that is reversed with the administration of prostanoids. PGF_{2α}, PGE₁, and PGE₂ all enhance detrusor contraction; PGE₁ and PGE₂ cause urethral relaxation, and PGF_{2α} results in urethral contraction ([Rahnama'i et al, 2012](#)).

The clinical studies conducted to date have demonstrated mixed outcomes ([Wagner et al, 1985](#); [Tammela et al, 1987](#); [Koonings et al, 1990](#); [Bergman et al, 1992, 1993](#)); however, a recent pooled analysis of the results of two randomized trials assessing PGE₂ and a third assessing PGF_{2α} demonstrated a statistically significant association between instillation and successful voiding (risk ratio 3.07) ([Buckley and Lapitan, 2010](#)). Both PGE and PGF series also stimulate contraction of the uterus, a potential side effect of treatment ([O'Brien, 1995](#)).

Future Prospects in Pharmacotherapy

In the absence of any effective compound, there are several avenues aimed at increasing bladder contractility that can be explored, as follows:

- Parasympathomimetics could yet be an option; however, their side-effect profile is concerning. Development of a bladder-specific agent could avoid these effects permitting dose escalation. However, this is unlikely to be possible based on contemporary knowledge.
- Novel muscarinic receptor manipulation such as postsynaptic allosteric receptor enhancement or the presynaptic M₂-receptor antagonist could be promising.
- Exogenous prostanoids require further investigation; agents with selectivity for the urinary tract over the uterus and gastrointestinal tract are under development; however, whether they will be effective if taken orally is an important question.
- Agonists of transient receptor potential (TRP) channels, such as TRPV4 agonist GSK1016790A, can increase contractility and are worthy of further investigation.

- Treatments of analogous conditions affecting other organ systems, such as cardiac inotropes in cardiac failure or prokinetics for intestinal dysmotility, could provide alternative options to increase contractility.
- Improving bladder sensation using sensory sensitizers could hypothetically help patients with impaired afferent signaling.

To develop effective drug therapies there is a need to better understand the pharmacologic principles that underpin normal detrusor contraction and the mechanisms of detrusor dysfunction underlying DUA.

Electrical Stimulation

A variety of electrical stimulation techniques have been applied in DUA of different causes. [Brindley and associates \(1982, 1986\)](#) developed the sacral root stimulator for patients with complete spinal cord injury to activate the anterior sacral roots and achieve volitional bladder emptying. For the procedure to be successful there is a need for intact peripheral efferents and the absence of myogenic dysfunction. This is confirmed by the presence of reflex detrusor contractions on bladder filling preoperatively. The anterior sacral roots are stimulated through an implantable receiver, stimulation wires, and external transmitter. Stimulation also activates urethral somatic efferents; this is overcome by using intermittent stimulation patterns that exploit the longer relaxation time of smooth muscle compared to skeletal muscle to generate a sustained detrusor contraction with short intermittent periods of sphincter contraction. Clinically this results in an interrupted void pattern. [Sauerwein \(1990\)](#) subsequently modified the technique by combining it with total sacral root rhizotomy, thereby abolishing all reflex activity.

[Katona and Berenyi \(1975\)](#) popularized the technique of applying electrical current to the bladder wall through a transurethral electrode in 1958, termed *intravesical electrotherapy* (IVE). The bladder is filled with saline, and current is passed through an electrode (cathode) at the tip of the catheter; the circuit is completed by a neutral electrode applied to the skin in an area of normal sensation. Daily sessions of stimulation are undertaken, usually of 1 hour or more, with 10 to 15 sessions considered a trial period.

Animal experiments have shown that IVE activates mechanosensitive bladder afferents (myelinated Aδ fibers) and, as a consequence, central reflex activation of the detrusor ([Ebner et al, 1992](#)). It is postulated that repeat activation of this pathway upregulates its performance during bladder filling and volitional voiding, resulting in improved sensation and emptying. On this basis, where the underlying cause is complete denervation or bladder wall fibrosis, IVE is considered unlikely to be successful.

IVE has been studied primarily in the pediatric age group, with some encouraging results, but is still considered a controversial therapy. There is considerable heterogeneity in inclusion criteria and technical aspects, and most studies include only small numbers, limiting definitive conclusions as to efficacy. In children with both neurogenic and idiopathic DUA, voiding was normalized after treatment in as many as 85% of cases ([Gladh, 2002](#)). In adults with predominately neurogenic DUA, 39% of those without a detrusor contraction and 75% without bladder sensation before treatment experienced a restoration of these parameters ([Primus et al, 1996](#)). Several studies have failed to show benefit, including the only sham controlled randomized prospective study ([Boone et al, 1992](#)). Moreover, IVE often is undertaken alongside an intensive bladder training/biofeedback regimen, which may partially explain the positive outcomes ([Madersbacher, 1990](#)). Although not associated with significant complications (except a small risk for UTI), its principal limitations are the significant time and resource requirements. An average of 47 sessions was required for a durable effect in a cohort of children followed for 10 years after treatment ([Kaplan, 2000](#)).

Sacral neuromodulation (SNM) was first introduced over 30 years ago by [Tanagho and Schmidt \(1982\)](#). It has been used with good efficacy in the group of patients with nonobstructive

urinary retention and DUA (Everaert et al, 1997; Swinn et al, 2000). It is postulated that abnormal afferent signals generated from the urethral sphincter (because of pelvic floor/sphincter disorders) have an inhibitory effect on bladder afferents at the level of the sacral spinal cord, preventing their transmission in the periaqueductal gray and higher brain centers. SNM is thought to inhibit urethral afferent signals and allow restoration of normal afferent flow to the brain and the resumption of normal bladder sensation and detrusor contractions. A direct effect on bladder efferents is possible but less likely (DasGupta and Fowler, 2004).

Botulinum Toxin

Botulinum neurotoxin A (BoNT-A) injected into the urethral sphincter has been used to reduce outlet resistance and improve bladder emptying in patients with detrusor-sphincter dyssynergia (Dykstra et al, 1988; Schurch et al, 1996; Phelan et al, 2001). The potential rationale for its use in DUA is to relax the urethral sphincter mechanism, thereby overcoming reflex inhibition of detrusor function (Park et al, 1997), or to facilitate Valsalva-induced voiding.

Kuo (2003) reported the results of urethral BoNT-A (50 U in 4 mL of normal saline) in 20 patients with DUA of mixed causes. The toxin was injected cystoscopically in men and periurethrally in women. Seven patients who previously required indwelling catheters could void with low PVRs (≤ 150 mL). In the 7 patients performing ISC at baseline it could be stopped or reduced in frequency after injection. The same author also reported the effects of urethral BoNT-A (50 U or 100 U in 4 mL and 8 mL of normal saline, respectively) in 27 patients (5 men and 22 women) with idiopathic detrusor underactivity (low or no Pdet and Qmax of <10 mL/sec and PVR >150 mL) (Kuo, 2007a). An increase in Pdet and Qmax with a decrease in PVR occurred in 13 patients (48%), all of whom could void without abdominal straining. Analysis of baseline characteristics identified the responders as having significantly better bladder sensation. Patients with evidence of poor sphincter relaxation before treatment were more likely to improve (87%) compared to patients with DUA only (33%) or DHIC (30%).

The evidence available suggests that the action of BoNT-A when injected into the urethral sphincter mechanism is short-lived, and to date no adequate clinical studies have been conducted to evaluate the appropriate dose. In this context it is not licensed for use and cannot be used outside of a clinical trial setting.

Surgery

Bladder Outlet Surgery

The role of bladder outlet surgery in the management of men with non-neurogenic DUA is a controversial topic in which there is a lack of high-level evidence to guide clinical decision making.

It is important to differentiate between two common clinical scenarios: the patient with DUA with a low or minimal PVR whose primary complaint is symptoms and the patient with DUA who is catheter dependent (i.e., chronic retention). In the former, although BOO cannot be definitively excluded, because of the limitations of urodynamic analysis discussed earlier, it is generally less likely to be significant as the patient is able to empty the bladder with a low Pdet. In this situation, outlet surgery is generally considered to be unlikely to significantly improve voiding LUTS. This supposition is supported by a study that followed 22 men with DUA treated with TURP for a mean of 11.3 years (Thomas et al, 2004). The majority of patients underwent TURP on the basis of symptoms (3 of 22 after acute retention). There was no significant improvement in any symptoms. A small reduction of questionable clinical significance in the BOO index ($\text{BOOI} = \text{Pdet@Qmax} - 2 \text{Qmax}$) did occur but was not associated with an improvement in flow rate or voiding efficiency. It can be concluded that when compared to patients with DUA undergoing conservative treatment, outlet surgery confers no significant improvement in symptoms or urodynamic

parameters. Other studies with shorter follow-up support these findings (Rollema and Van Mastrigt, 1992; Javle et al, 1998).

In the situation in which the patient with DUA is catheter dependent and has arguably reached a later stage of detrusor decompensation, even less evidence is available as to the benefit of outlet surgery. Surgery is performed with the aim of reducing outlet resistance enough to permit bladder emptying, albeit the flow rate and PVR rarely return to normal in this scenario. Predictors of poor outcome include low voiding pressures (<45 cm H₂O) (Ghalayini et al, 2005), older age (>80 years), and high residual volume (>1500 mL) (Djavan et al, 1997). Although the limited evidence suggests men with DUA and chronic retention do less well after bladder outlet surgery (Ghalayini et al, 2005), a significant proportion resume spontaneous voiding (Monoski et al, 2006). In the absence of any other effective treatments some advocate surgery in the younger, medically fit patient who wishes to become catheter free.

The use of urethral dilation for women with DUA and significant residuals has been advocated but lacks an adequate evidence base to permit clear conclusions to be drawn (Basu and Duckett, 2010). Resection or incision of the bladder neck in women with DUA is not recommended, because this may lead to significant problems with either incontinence or bladder neck stenosis.

Urinary Diversion

Because of the general acceptability and safety of both ISC and indwelling catheterization techniques, urinary diversion is rarely performed for DUA outside of the neurogenic population. When urethral clean intermittent catheterization is not possible and the patient wishes to avoid a suprapubic catheter, as is often the case in young women with idiopathic urinary retention refractory to SNM, a continent catheterizable stoma can be performed. An incontinent diversion (e.g., ileal conduit) is occasionally performed when there are signs of renal deterioration resulting from obstruction to the intramural ureters secondary to a thick-walled bladder.

Reconstructive Surgery

Few reports of reconstructive surgical procedures for DUA are available. Stenzl and colleagues (1998) reported the first series of latissimus dorsi detrusor myoplasty in patients with DUA in 1998. The muscle is harvested, and its pedicle is anastomosed to the inferior epigastric vessels, with the nerve coapted to the intercostal branch. The muscle is wrapped in a spiral configuration around the bladder, covering over three quarters of its surface. It is then anchored to the pelvic floor fascia and ligaments. The long-term outcomes of this technique in 24 catheter-dependent patients with acontractile detrusor have been reported (Gakis et al, 2011). Seventeen patients recovered the ability to void (mean PVR = 25 mL). The mean bladder contractility index increased from 20.1 ± 7.6 to 176.2 ± 25.4 ($P < .001$). Complications occurred in a third of patients, including thromboembolism, pelvic abscess, and wound infection, though there were no long-term problems. Partial cystectomy (or reduction cystoplasty) has been reported as an alternative approach, in a few series (Weinberg et al, 1974; Klarskov et al, 1988), with no recent reported studies and is no longer considered in contemporary practice.

CONCLUSIONS

DUA is a not uncommon problem that can pose a difficult challenge for both patients and physicians because of the lack of simple and effective treatments. This problem has received little attention in clinical and basic science research in comparison to other common LUTD such as OAB and DOA. Defining the problem in symptom-based terms is difficult because of the wide spectrum of manifesting symptoms, underlying clinical conditions, and absence of accurate noninvasive markers. Clinical studies suggest that the problem is highly prevalent in both men and women with LUTS

KEY POINTS: MANAGEMENT

- There are no effective pharmacotherapies for the treatment of DUA.
- Parasympathomimetic agents have questionable efficacy, are associated with potentially fatal systemic effects, and are not used in routine practice.
- Intravesical electrotherapy has shown promising results in restoring detrusor contraction; however, it is time- and resource-consuming.
- SNM is effective in restoring voiding in patients with DUA associated with urethral sphincter/pelvic floor disorders.
- Bladder outlet surgery has a high risk for failure in men with DUA not reliant on catheters. Men with DUA and chronic retention dependent on catheter drainage experience poorer outcomes than those with normal detrusor function; however, they still may benefit from surgery.

presenting to urologists. A variety of causes are implicated, affecting all aspects of the micturition reflex. There is a lack of any simple and effective treatments. Preserved bladder sensation appears to predict better responses to treatment. There is need for a greater understanding of the mechanisms governing normal detrusor con-

traction and how these are affected by disease. Until this is achieved it will be difficult to develop compounds that enhance detrusor strength and duration of contractility or enhance bladder sensation. In the future developments in regenerative medicine, stem cell and gene therapy may provide interesting avenues for further research, but a prerequisite for this will be to develop a better understanding of both normal structure and function of the LUT and the way in which this is altered in cases of DUA.

Rationale for Evaluation and Management

Evaluation

Nocturia, defined as waking because of the desire to void during intended sleep, can be the result of an abnormality in the genitourinary tract or a symptom of an underlying medical condition. Because of its numerous causes, uncovering the cause of a patient's nocturia and treating it appropriately can be a diagnostic and therapeutic challenge for the urologist. A systematic approach, including a thorough history and physical examination, is essential to help find the underlying cause(s). Therapeutic options are numerous and include conservative/behavioral management, pharmacotherapy, phytotherapy, and invasive procedures. Tailoring appropriate therapy to an accurate diagnosis should lead to effective treatment and patient satisfaction.

RATIONALE FOR EVALUATION AND MANAGEMENT

Nocturia Is Bothersome

The International Continence Society (ICS) defines **nocturia as voiding that occurs during the hours of sleep (i.e., voiding that is preceded and followed by sleep)** (van Kerrebroeck et al, 2002). Key terms are listed in Table 78-1. Some clinicians do not consider one void during the night to be clinically significant. This may be because several studies have shown that less than two voids per night does not generate bother and that two or more voids per night can impair quality of life (Häkkinen et al, 2006; Hernández et al, 2008; Tikkinen et al, 2009b). **The definition of nocturia does not take into account the patient's degree of bother.** For example, one patient who voids once per night may report being very bothered versus another patient who voids 2 or 3 times per night who may report little bother. **Degree of bother influences quality of life.** According to the Boston Area Community Health (BACH) Survey, a population-based study of 5502 men and women 30 to 79 years of age, nocturia is associated with a decreased quality of life and an increased prevalence of depressive symptoms in both men and women (Kupelian et al, 2012). Compared to those with low bother, patients reporting high levels of nocturia-specific bother were found to be significantly more likely to have difficulty initiating sleep (47.7 minutes \pm 34.4 vs. 23.5 minutes \pm 13.6, $P = .05$), difficulty returning to sleep (28.9 minutes \pm 16.1 vs. 15.4 minutes \pm 9.6, $P = .03$), and greater morning fatigue (3.3 \pm 0.7 vs. 2.5 \pm 1.0, $P = .04$). Subjective morning fatigue and sleep ratings scale ranges from 1 to 7; higher scores equate to worse fatigue or sleep characteristics (Vaughan et al, 2012). In a prospectively analyzed study of various sleep parameters and nocturia in a cohort of community-dwelling men and women, nocturia, common among older individuals with insomnia, was associated with both increased subjective nocturnal and decreased daytime wakefulness (Zeitzer et al, 2013).

Nocturia Is Common

Nocturia affects people of different ages, races, and genders all over the world. The BACH Survey, composed of 5502 men and women

Cause and Management

between the ages of 30 and 79, found that the overall **prevalence of nocturia (>1 void per night) was 28.4%, 25.2% among men and 31.3% among women** (Fitzgerald et al, 2007). A review of 43 pertinent articles revealed that prevalence rates of nocturia in younger men (20 to 40 years) were one or more voids in 11% to 35% and two or more voids in 2% to 17%. In older men (>70 years), rates were one or more voids in 69% to 93% and two or more voids in 29% to 59%. Prevalence rates in younger women were one or more voids in 20% to 44% and two or more voids in 4% to 18%. In older women, rates were one or more voids in 74% to 77% and two or more voids in 28% to 62%. It is noteworthy that **one in every five or six people 20 to 40 years of age wakes two or more times per night and that up to nearly three in every five people older than 70 years wake to void two or more times nightly** (Bosch and Weiss, 2010). The Fujiwara-Kyo study included 4427 men and women over the age of 65. Nocturia was defined as awakening to void two or more times per night. In this population, the prevalence was reported to be 47% at baseline and 50% 1 year later. The incidence was found to be 20% and the remission rate was 15%. The authors showed that women and younger patients were more likely to spontaneously remit (Hirayama et al, 2013).

The prevalence of nocturia in both men and women increases with age (Bosch and Weiss, 2010). In a survey of 1424 elderly individuals (ages 55 to 84 years), 53% of the sample listed nocturia as a self-perceived cause of nocturnal sleep disturbance every night or almost every night (Bliwise et al, 2009). Data acquisition methodology regarding nocturia may influence calculated prevalence. In the Krimpen study, a Dutch cohort of community-dwelling men 50 to 78 years of age, the International Prostate Symptom Score (IPSS) nocturia question overestimated the percentage with nocturia three times or more compared with recordings on frequency-volume charts, in younger men (younger than 60 years). In contrast, older men (older than 60 years) underestimated their nighttime frequency when scoring the IPSS nocturia question. Nocturia was three times more prevalent in men with a low functional bladder capacity (<300 mL) in the Krimpen study than men with greater capacity (Bosch and van Doorn, 2012).

Association of Nocturia with Early Mortality

Nocturia affects both quality and quantity of life. Several studies have implicated nocturia in overall survival. In the Third National Health and Nutrition Examination Survey (NHANES III), a U.S. population-based sample of 7455 men and 8533 women, two or more voids per night were associated with worse survival compared to zero to one voids per night. This was particularly true in subjects younger than 65 years of age (Kupelian et al, 2011). In a community sample of 784 Japanese individuals 70 years or older, subjects with nocturia were at greater risk for skeletal fracture and death than those without nocturia during the 5-year observation period (even when adjusting for covariates including diabetes, smoking status, history of coronary disease, renal disease, and stroke and use of

TABLE 78-1 Key Terms and Definitions

TERM	DEFINITION
Night	The period between going to bed with the intention of sleeping and waking with the intention of arising
Nocturia	Waking one or more times to void during the hours of sleep; each void is preceded and followed by sleep
Total urine volume (TUV)	Total volume of urine produced during a 24-hour period
First morning void	The first void after waking with the intention of rising
Nocturnal urine volume (NUV)	Total volume of urine passed during the night, including the first morning void
Maximum voided volume (MVV)	The largest single voided volume in a 24-hr period
Nighttime frequency or actual number of nightly voids (ANV)	The number of voids recorded from the time the individual goes to bed with the intention of sleeping, to the time the individual wakes with the intention of rising
Nocturia index (Ni)	$Ni = NUV/MVV$; when $Ni > 1$ NUV exceeds maximum storage capacity and nocturia or enuresis occurs
Nocturnal polyuria	Nocturnal volume $>20\%$ – 33% of total 24-hr volume (age dependent), other definitions include: NUV >6.4 mL/kg NUV >0.9 mL/min (54 mL/hr) NUV >1.5 mL/min (>90 mL/hr)
Nocturnal polyuria index (NPI)	$NPI = NUV/TUV$; if $NPI > 0.20$ – 0.33 (age dependent); patient has nocturnal polyuria
Predicted number of nightly voids (PNV)	$PNV = Ni - 1$, used for calculation of NBCi
Nocturnal bladder capacity index (NBCi)	$NBCi = ANV - PNV$; $NBCi > 0$ indicates that nocturia will occur at voided volumes $< MVV$. $NBCi > 2$ associated with severe nocturia
Global polyuria	24-hour voided volume of >2.8 L in a 70-kg adult (>40 mL/kg)
Nocturnal enuresis	Voiding occurring during sleep

Modified from van Kerrebroeck P. Standardization of terminology in nocturia: commentary on the ICS report. BJU Int 2002;90(Suppl 3):16–7.

tranquilizers, hypnotics, and diuretics) (Nakagawa et al, 2010). In contrast, the Krimpen study, here analyzing 1114 men 50 to 78 years of age based on frequency-volume chart data, determined that the association between nocturia and mortality was explained by confounding factors including age, chronic obstructive pulmonary disease, smoking, and hypertension (age being the most profound). Specifically, nocturia was associated with increased mortality in the univariate analysis, but was not associated with mortality in multivariate analysis (van Doorn et al, 2012).

Nocturia affects sleep efficiency and sleep latency. Sleep efficiency is defined as actual time asleep (minutes) divided by total time of intended sleep (minutes); normal is considered greater than 85%. Sleep latency is defined as the time it takes to go from being completely awake to being completely asleep. Dew and colleagues (2003) showed that older adults with certain electroencephalography (EEG) sleep characteristics have an increased risk for dying independent of age, gender, and medical comorbidities. Individuals with sleep latency times of greater than 30 minutes were found to have greater than twice the risk for death, and those with sleep efficiency less than 80% were found to have nearly twice the risk for death when controlling for age, gender, and medical burden. Vaughan and associates (2013) prospectively analyzed 63 patients with Parkinson disease using IPSS and polysomnography. Of the 60 having completed the IPSS, 37 (61%) reported two or more episodes of nocturia. These patients demonstrated lower polysomnography-defined sleep efficiency and whole-night total sleep time than patients with zero to one episode of nocturia per night. Also, patients who reported two or three episodes of nocturia with high bother on the IPSS demonstrated lower whole-night total sleep time (281 ± 116 minutes vs. 373 ± 59 minutes, $P = .03$) and worse sleep efficiency ($59\% \pm 23\%$ vs. $76\% \pm 11\%$, $P = .04$) compared to participants who reported two or three episodes of nocturia with low bother. These results show that individuals with higher

bother on the IPSS experience poorer sleep as defined by polysomnography and that patients with Parkinson disease and nocturia have poor sleep in general.

It is not surprising that nocturia is associated with an increased risk for mortality, because nocturia can be a symptom of serious systemic illnesses including hypertension, diabetes, heart disease, and kidney disease (Ancoli-Israel et al, 2012). Sleep loss can negatively affect health by decreasing immune function, increasing the risk for cardiovascular disease, and increasing the risk for developing obesity and type 2 diabetes (Spiegel et al, 2004; Asplund, 2005). This can be better understood by defining the various states and stages of sleep. Sleep is divided into two states: rapid eye movement (REM) and non-rapid eye movement (NREM). NREM accounts for approximately 75% of total sleep time and is divided into 4 stages. Stage 1 accounts for the transition from wakefulness to sleep; stage 2 accounts for light sleep; and stages 3 and 4 consist of deep, restorative sleep or slow-wave sleep (SWS) (Keenan, 1999). The normal sleep cycle alternates between stages 1 and 4 of NREM and REM sleep (Roehrs, 2000). Each night consists of roughly four to six sleep cycles. In the beginning of the night, SWS predominates, whereas in the later hours of the night REM predominates. Waking up during REM sleep is more natural and may still leave one feeling rested compared to waking during SWS, which leaves one to experience daytime fatigue and discomfort irrespective of the total length of sleep time (Lentz et al, 1999). Because the first nocturia episode often occurs within the first 2 to 3 hours of sleep on average, SWS may be interrupted by nocturia, which may explain why nocturics often experience decreased quality of life (van Kerrebroeck et al, 2007).

SWS plays a role in glucose homeostasis. Tasali and colleagues (2008) demonstrated that suppression of SWS for 3 nights impairs glucose tolerance and insulin sensitivity. This explains why aging individuals with impaired SWS are at higher risk for developing type

2 diabetes. The body's regulation of SWS is a homeostatic process as well. This was illustrated by a study that monitored the EEG activity of both control subjects and subjects receiving acoustic stimulation during the first 3 hours of sleep to decrease the amount of SWS. Individuals who had decreased SWS early in the night because of acoustic stimulation were noted to have inadequately compensated amounts of SWS later in the night (Dijk, 2009). In a related study, when the first void occurred during the first two sleep cycles, patients had (on average) 37 minutes of SWS compared to those in whom the first void occurred after the first two sleep cycles, tallying (on average) 56 minutes of SWS ($P = .023$). The actual number of nightly voids (ANV) also affected SWS. Patients who experienced no to one void per night had an average of 62 minutes of SWS compared to those who experienced two or more voids per night, who had an average of 40 minutes of SWS ($P = .014$) (Torimoto et al, 2013). In the Sleep Heart Health Study, 2813 men and 3097 women between the ages of 40 and 100 years of age were enrolled in a community-based prospective study that examined the cardiovascular consequences of sleep-disordered breathing. Usual sleep durations were obtained by questionnaire, and hypertension was defined as systolic BP greater than 104 mm Hg, diastolic BP greater than 90 mm Hg, or the use of medication to treat hypertension. Usual sleep duration above or below the median of 7 to 8 hours per night was associated with an increased risk for hypertension, particularly in individuals who sleep less than 6 hours per night (Gottlieb et al, 2006). **Sleep duration less than 6 hours or more than 8 hours may be a factor predisposing to the metabolic syndrome.** Compared to those sleeping 7 to 8 hours per night, those sleeping longer or shorter were at least 45% more likely to have metabolic syndrome (Hall et al, 2008). A recent analysis of the BACH survey revealed that among baseline lower urinary tract symptoms (LUTS), only nocturia was associated with incident sleep problems at 5-year follow-up (odds ratio [OR] 1.98 with or without body mass index adjustment, $P < .001$) (Araujo et al, 2014). In a U.S. cohort of 2447 men (40 to 79 years of age) who were followed for a median of 17.1 years, nocturia was found to be a marker for coronary heart disease in men younger than 60 years (adjusted OR 1.36) and a marker for death in men 60 years of age or older (OR 1.48) (Lightner et al, 2012). **In summation, present evidence points to nocturia as a risk factor for future development of both metabolic syndrome and early mortality owing to its proxy effect on sleep impairment.**

Nocturia is among the LUTS most strongly associated with falls (Parsons et al, 2009) and is a risk for hip fractures (regardless of age). In an Austrian study, 1820 men 40 to 80 years of age completed the IPSS. Although the IPSS was not correlated with the occurrence of hip fractures, nocturia (two or more voids per night) was an age-independent risk factor for hip fractures (OR 1.36; 95% confidence interval [CI] 1.03, 1.80; $P = .03$) (Temml et al, 2009). Hip fractures have been associated with an in-hospital mortality rate of 5.3%, hence providing explanation for early mortality related to nocturia (Alvarez-Nebreda et al, 2008). What is not clear is whether successful therapy for nocturia could diminish falls, fractures, metabolic syndrome, or early mortality.

Costs to Society

Assuming that 28 million people 25 years of age or older in the United States experience nocturia (more than two voids per night) and this results in a productivity loss of 127 hours per individual, then based on the average U.S. wage of \$17.38 per hour (based on small-size, private industry salaries), the economic value of productivity lost in 2008 was \$61 billion (Holm-Larsen et al, 2010). In a Swedish study, productivity, vitality, and quality of life were assessed in more than 200 professionally active adults with one or more voids per night. Compared with controls, patients with nocturia had significantly increased work impairment (assessed using a work productivity and activity impairment questionnaire) and increased impairment in nonwork activities ($P < .001$). Patients with nocturia also had significantly reduced vitality (based on responses to Short Form-36) and reduced overall quality of life (based on responses

to EQ-5D) compared with controls ($P < .001$). It also was found that work impairment increased and vitality decreased in proportion to nocturia severity ($P < .05$, $< .01$ respectively) (Kobelt et al, 2003). Nocturnal awakenings were found to be associated with sleepiness, naps, and sick leave in the general adult population in a study in which 76% of respondents reported needing to go to the toilet as the reason for awakening (i.e., true nocturia) (Ohayon, 2008).

KEY POINTS: RATIONALE FOR EVALUATION AND MANAGEMENT

- Nocturia is waking during intended sleep because of the desire to void.
- Two or more voids per night appears to be clinically significant.
- The prevalence of nocturia increases with age.
- Nocturia is costly to society because it can lead to decreased productivity, increased time away from work, and increased falls and fractures.
- Nocturia impairs sleep efficiency, sleep latency, and SWS and is associated with increased mortality.
- Nocturia can be a symptom of serious systemic illness, including hypertension, diabetes, heart disease, and kidney disease, leading to metabolic syndrome.

EVALUATION

The cause of nocturia can be multifactorial and complex; therefore the evaluation of nocturia should be thorough and systematic, beginning with a complete history and physical examination. By way of example, a history of medication use, such as lithium, should alert the clinician to the possibility of global polyuria as a result of drug-induced nephrogenic diabetes insipidus. Physical findings pertinent to an evaluation of nocturia might include peripheral edema resulting from cardiac disease, nephrotic syndrome, or venous insufficiency and be associated with nocturnal polyuria. Physical findings such as obesity and short neck might be suggestive of obstructive sleep apnea (OSA); the latter also is associated with nocturnal polyuria. In the population-based Finnish National Nocturia and Overactive Bladder (FINNO) study, numerous risk factors for nocturia were identified, such as urinary urgency, benign prostatic hyperplasia (BPH), snoring, obesity, antidepressant usage, restless leg syndrome, and prostate cancer in men and obesity, urinary urgency, snoring, diabetes, restless leg syndrome, and coronary artery disease in women. However, none of the identified risk factors were associated with nocturia in more than 50% of the affected subjects of both sexes, highlighting the multifactorial cause of nocturia (Tikkinen et al, 2009a). Hence, it is essential that clinicians consider factors beyond the LUT when treating bothersome nocturia.

Some of the questions to consider when evaluating nocturia are: How is nighttime defined? Is the patient awakened by the need to void, or does the patient void because he or she is already awake? A recent study by Weinberger and coworkers (2013) showed that 92% of men and 90% of women are awakened by the urge to void, leaving the remainder as incidental nocturnal convenience voids. **Nighttime is defined as the period between going to bed with the intention of sleeping and waking up with the intention of arising** (van Kerrebroeck et al, 2002). This definition becomes relevant when explaining to the patient how to complete a 24-hour voiding diary or **frequency-volume chart**, the most valuable objective instrument in evaluating nocturia. When completing a frequency-volume chart, the patient must be aware that nocturnal voids are preceded and followed by the intention of sleep regardless of time of day. Because at least 16% of the U.S. population consists of shift workers who occasionally sleep during the day, it is important to remember that nocturia may occur during the day (Beers, 2000). Changing time zones (jet lag) also complicates the

definition of nighttime. Before having a patient complete a frequency-volume chart, it is best to allow sufficient recovery time to eliminate the effect of jet lag.

Although the first morning void after a night's sleep is counted toward daytime (diurnal) frequency rather than the ANV, the volume of the first morning void is included in the tally of nocturnal voided volume. Hence, nocturnal urine volume (NUV) is the sum of all nocturnally voided volumes plus that of the first morning void, because the urine in the latter void is produced during the hours of sleep. An untested assumption is that most patients void before bedtime. Hence the first nocturia-related void is also assumed to have been excreted during the hours of sleep. **Maximum voided volume (MVV)** is the largest voided volume of urine during a 24-hour period. The nocturia index (Ni) is calculated by dividing NUV by MVV (Weiss et al, 1999). When NUV is greater than MVV, the Ni is greater than 1, in which case nocturia must occur if the patient awakens and, if not, enuresis will occur.

Nocturnal polyuria is increased production of urine at night that is offset by lowered daytime urine production, such that 24-hour urine volume remains within normal limits (Asplund, 1995). Because urine is normally produced in an age-dependent circadian pattern, it is worthwhile to determine the nocturnal polyuria index (NPI), which is the percentage of urine produced during nighttime (calculated as $\text{NUV}/\text{total 24-hour urine volume}$). In healthy adults 21 to 35 years of age, mean NPI = 0.14 versus patients aged 65 years and older, whose mean NPI = 0.34 (Rembratt et al, 2002). The NPI for middle-aged adults lies between 0.14 and 0.34. Accordingly, to simplify the definition, the ICS has defined NP as NPI greater than 20% (0.20) in young adults and greater than 33% (0.33) in patients older than 65 years when 24-hour urine production is within normal limits (van Kerrebroeck et al, 2002). Other definitions of nocturnal polyuria include NUV greater than 6.4 mL/kg and NUV greater than 0.9 mL/min (54 mL/hr) (Matthiesen et al, 1996). Blanker and associates (2002) defined nocturnal polyuria as greater than 1.5 mL/min (>90 mL/hr), which was 2 standard deviations above the mean of 60 mL/hr in their study of men 50 to 78 years of age. Van Doorn and colleagues (2013) found that prevalence, incidence, and resolution rates of nocturnal polyuria vary greatly depending upon which definition is used. When analyzing the cohort of 1688 men 50 to 78 years of age in the Krimpen study, men who had nocturnal polyuria defined as nocturnal urine production greater than 90 mL/hr (NUP90) had a baseline prevalence of 15.0% that increased to 21.7% after 6.5 years. When nocturnal polyuria was defined as NUV greater than 33% of 24-hour voided volume (NUV33), baseline prevalence was 77.8% and increased to 80.5% after 6.5 years. At baseline, NUV33 was prevalent in 91.9% of men with nocturia and in 70.1% of men without nocturia and NUP90 was prevalent in 27.7% of men with nocturia and 8.0% of those without nocturia (van Doorn et al, 2013). A universally accepted definition of nocturnal polyuria has yet to be defined.

Another cause of nocturia is **decreased bladder capacity**. This can result from either a global decrease in bladder capacity as expressed by a low MVV or simply a decrease in nocturnal bladder capacity. In both instances, NUV exceeds nocturnal bladder capacity and the patient arises because of the need to void. The **nocturnal bladder capacity index (NBCi)** is a useful means to examine the relationship between the patient's own bladder capacity and nocturnal voided volumes during a 24-hour period. NBCi is calculated by subtracting the predicted number of nightly voids (PNV) from the ANV. The PNV is calculated by subtracting 1 from Ni or (NUV/MVV). If Ni is greater than 1, nocturia occurs because functional bladder capacity (MVV) is exceeded. Therefore $\text{PNV} = (\text{Ni} - 1)$ and $\text{NBCi} = (\text{ANV} - \text{PNV})$. If NBCi is greater than 0, then nocturia occurs at volumes less than MVV (Weiss, 2012). As an example, a patient who voids eight times per night (ANV = 8), who voids a total of 800 mL during the intended hours of sleep (NUV = 800 mL), and who has an MVV of 200 mL would have an Ni of 4 ($\text{Ni} = \text{NUV}/\text{MVV} = 800 \text{ mL}/200 \text{ mL} = 4$). This patient's $\text{PNV} = \text{Ni} - 1 = 4 - 1 = 3$. Therefore this patient's $\text{NBCi} = \text{ANV} - \text{PNV} = 8 - 3 = 5$. An NBCi of 5 indicates a substantially diminished nocturnal bladder capacity. Although there is a significant association between patients with

severe nocturia and NBCi greater than 2 (Weiss et al, 1999), an analysis of a sample of normal volunteers suggested that nocturia is related to diminished nocturnal bladder capacity when NBCi is greater than 1.3 (Burton et al, 2011).

Global polyuria also can cause an individual to wake to void during the hours of sleep. **Global polyuria is defined as 24-hour urine output greater than 40 mL/kg causing both daytime urinary frequency and nocturia** (Oelke and van Kerrebroeck, 2012). For example, a 75-kg patient would be considered to have global polyuria if the 24-hour urine output exceeded 3000 mL ($75 \text{ kg} \times 40 \text{ mL/kg} = 3000 \text{ mL}$). It is worthwhile to note that nocturia can have a mixed cause, as well; that is, a patient may awake to void during the hours of sleep because of diminished nocturnal bladder capacity combined with either nocturnal polyuria or global polyuria.

KEY POINTS: EVALUATION

- A thorough evaluation of nocturia should include a complete history and physical examination.
- A frequency-volume chart or a voiding diary is the single most useful tool in evaluating and classifying the cause of nocturia.
- When NUV is greater than MVV, the Ni is greater than 1, and nocturia will occur if the patient awakens. If the patient does not awaken, enuresis will occur.
- Nocturnal polyuria is increased production of urine at night and has several definitions.
- Global polyuria is defined as 24-hour urine output greater than 40 mL/kg causing both daytime urinary frequency and nocturia.

CAUSE AND MANAGEMENT

Classification of nocturia using a frequency-volume chart, along with a thorough history and physical examination, unlocks up to 17 different underlying medical conditions that may potentially contribute to its genesis (Table 78-2). Diary-based classification of

TABLE 78-2 Diary-Based Classification of Nocturia and Respective Underlying Medical Conditions

NOCTURIA CATEGORY	UNDERLYING MEDICAL CONDITIONS
Nocturnal polyuria	Excessive nighttime fluid intake Peripheral edema Obstructive sleep apnea Diabetes mellitus Congestive heart failure
Diminished global or low nocturnal bladder capacity	Ureteral calculi Bladder calculi Pharmacologic agents Anxiety disorders Learned voiding dysfunction Cancer of bladder, prostate, or urethra Neurogenic bladder Nocturnal detrusor overactivity Prostatic obstruction
Global (24 hour) polyuria	Primary polydipsia Diabetes insipidus Diabetes mellitus

nocturia also can help the urologist follow a treatment algorithm (Fig. 78-1). Although unproved, it is assumed that more accurate classification leads to better treatment outcomes.

Nocturnal Polyuria

Epidemiology and Causes

The definition of nocturnal polyuria has a major impact on its perceived prevalence. Among patients with nocturia, nocturnal polyuria seems to be quite common. In a population recruited for a pharmacologic study of nocturia, 819 (88%) of 934 subjects with nocturia (more than two voids per night) who completed a voiding diary had nocturnal polyuria (NUV >33% of 24-hour volume) (Weiss, 2009). On the other hand, in analyzing the Krimpen database, Blanker and associates (2000) found that nocturnal polyuria prevalence for men 50 to 54 and 65 to 69 years of age was 44% and 54%, respectively, at baseline and increased to 51% and 65% after 6.5 years of follow-up when nocturnal polyuria was defined

as NUV/24-hour urine volume greater than 33%. When the nocturnal polyuria definition was changed to NUV greater than 90 mL/hr, the prevalence for men 50 to 54 and 65 to 69 years of age was 14% and 23% and increased to 19% and 26%, respectively, after 6.5 years of follow-up. In an effort to prevent the overestimation of nocturnal polyuria prevalence, van Haast and Bosch (2012) proposed that nocturnal polyuria exists when the NP_i exceeds 53%.

The physiology of renal water handling is relevant to an understanding of the pathophysiology of nocturnal polyuria and its treatment. Normal circadian urine production is age dependent. In those younger than 25 years of age, NUV/total = 14%, and in those older than 65 years of age, NUV/total = 34% (Rembratt et al, 2002). Water is the largest component of the human body; the major determinant of body water is arginine vasopressin (AVP)-regulated water excretion by the kidneys. AVP is stimulated by high serum hyperosmolality, hypovolemia, and angiotensin II and is inhibited by natriuretic peptides and negative feedback via baroreceptors. AVP causes vasoconstriction via V_{1a} receptors and causes renal reabsorption of water through its action on V₂ receptors as follows: AVP

Figure 78-2. Schematic diagram depicting arginine vasopressin regulation of water reabsorption from renal tubular cells. Schematic representation of aquaporin 2 trafficking within a cell. AC, adenyl cyclase; AQP, aquaporin; ATP, adenosine triphosphate; cAMP, cyclic 3'-5'-adenosine monophosphate; PKA, protein kinase A; V₂R, V₂ receptor. (From Nielsen S. Renal aquaporins: an overview. *BJU Int* 2002;90[Suppl. 3]:1-6.)

stimulation of V₂ receptors, located in the basolateral membrane of the renal tubular cell, activates a G_s subtype of guanine nucleotide-binding protein (guanosine triphosphate [GTP]), which in turn activates adenylate cyclase. The result is an increased concentration of cyclic 3'-5'-adenosine monophosphate (cAMP), as well as activation of protein kinase A (PKA). PKA triggers the vesicles that contain aquaporin 2 (AQP2) to fuse with the luminal plasma membrane of the collecting tubule, thereby allowing water to enter the cell. Passive resorption of water through the basolateral membrane (aquaporins 3 and 4) along osmotic gradients by way of other water channels into the vasa recta ultimately leads to water retention (Fig. 78-2). Other factors that inhibit ADH and cause diuresis (inhibit water reabsorption) include prostaglandin E₂ (PGE₂), atrial natriuretic peptide (ANP), hypercalcemia, hypokalemia, lithium, and tetracyclines (Nielsen et al, 1999). Reversal of water diuresis, accordingly, may occur through stimulation of V₂ receptors, either by endogenous AVP or a congener thereof, such as desmopressin. Therefore low antidiuretic hormone (ADH) levels cause a larger volume of dilute urine to be produced. During sleep hours, this translates into a greater likelihood for nocturia.

OSA is a common cause of nocturnal polyuria. OSA is defined as the sudden cessation of respiration during sleep because of airway obstruction. Older adults with severe sleep disordered breathing have a greater number of nocturia episodes (Yalkut et al, 1996; Endeshaw et al, 2004). The mechanism behind this is as follows. Increased airway pressures lead to hypoxia, which in turn causes pulmonary vasoconstriction, the latter leading to increased right atrial transmural pressure with resulting increase in ANP production and ultimately increased renal sodium and water excretion. OSA is more likely as nocturia worsens in severity; the sleep apnea incidence in men with no, one, two, and three or more episodes of nocturia is 10%, 13%, 17%, and 20%, respectively. The sleep apnea

incidence in women with no, one, two, and three or more episodes of nocturia is 7%, 9%, 12%, and 19%, respectively (Hashim et al, 2011). Those with three or more voids per night are more likely to have severe OSA (Kaynak et al, 2004).

Management

Treating nocturnal polyuria should begin with a conservative approach. Directly address the nocturnal polyuria itself by recommending cessation of fluid intake 4 hours before bedtime, the use of compressive lower extremity stockings and/or administration of diuretics in the mid-afternoon for edema states, and antidiuretic therapy at bedtime. Individuals who have insomnia and nocturia may benefit from behavioral therapy directed at improving the insomnia. Tyagi and associates (2014) showed that individuals with insomnia and nocturia saw a greater improvement in number of nocturnal voids when treated with behavioral therapy versus receiving printed materials (information control). The behavioral therapy group saw a decrease in total number of nocturnal voids by 6.5 ± 4.8 over a 14-day period, whereas the information control group saw an increase of nocturnal voids by 1.3 ± 1.7 ($P = .05$). In addition, treating sleep disturbances, hypertension, and obesity in patients with nocturia also may decrease the number of nightly voids and improve quality of life (Sağlam et al, 2013).

A large roster of pharmaceutical agents may contribute to nocturia (Box 78-1). Further, timing of certain medications can influence nocturnal urine output. Diuretics work by preventing water accumulation and forcing water out of the system; they are indicated in patients with lower limb venous insufficiency and congestive cardiac failure. Timing of diuretic administration should be during the mid-afternoon, to allow for elimination of lower extremity excess body fluid during normal waking hours. In a small

randomized double-blind, placebo-controlled trial, 49 men (older than 50 years of age) with nocturnal polyuria were randomized to receive 40 mg of furosemide 6 hours before sleep versus placebo. Among the 43 men who completed the study, the reduction in nocturnal episodes was 0.5 versus 0.0 (furosemide vs. placebo, $P = .014$). There was also a significant reduction in percentage of nighttime voided volume: –18% versus 0% (furosemide vs. placebo, $P <$

.001). Therefore men with nocturnal polyuria may benefit from diuretic therapy 6 hours before sleep (Reynard et al, 1998).

Imipramine is a tricyclic antidepressant with a complex pharmacologic profile, including nonsubtype-selective antimuscarinic effect, also shown to have varied effects in modulating AVP release and potentiating renal proximal tubular sodium and water reabsorption in children. (Tomasi et al, 2001). Imipramine should be used with caution because it has been shown to prolong the PR, QRS, and QTc intervals, increase heart rate, and lower T-wave amplitude during a 4-week treatment course (Giardina et al, 1979). There have been rare reports of torsades de pointes and sudden death resulting from imipramine administration (Swanson et al, 1997).

The influence of nocturnal polyuria on nocturia therapy with antimuscarinics has been addressed in four pooled 3-month phase III randomized control trials, in which 2534 of 3032 patients reported nocturia at baseline (62% of these patients were classified as having nocturnal polyuria). These patients were randomized to receive solifenacin 5 mg, 10 mg, or placebo. In patients without nocturnal polyuria there was a statistically significant reduction in nocturia: –0.18 episode reduction advantage for 5 mg versus placebo and –0.18 episode reduction advantage for 10 mg versus placebo. Nocturia episode reduction in patients with nocturnal polyuria was not significant. However, failure to achieve statistically significantly decreased nocturia between drug and placebo in the nocturnal polyuria group appeared to be due to unexpectedly high performance of placebo in the latter arm (Brubaker and Fitzgerald, 2007).

Weiss and colleagues (2012) defined a clinically significant improvement in nocturia as one that improves the Nocturia Quality of Life (N-QoL) score. The N-QoL questionnaire consists of 13 statements in two domains (sleep/energy and bother/concern). Patients ranked each statement from 1 (lowest QoL) to 4 (highest QoL). One fewer nocturnal void was associated with a 4.68 increase in total N-QoL score, and a 1-hour increase in the first period of undisturbed sleep was associated with a 3.68 increase in total N-QoL. This study revealed that reducing nocturia improves quality of life.

Bal and coworkers (2012) found that nocturia mainly occurs during superficial/REM sleep and that OSA severity is directly related to both nocturia severity and daytime sleepiness and inversely related to sleep efficiency and total sleep time. **Treatment of OSA with continuous positive airway pressure (CPAP) can improve nocturia.** In a study of 88 men with OSA, the average number of nightly voids before treatment was 3.8 ± 0.4 voids per night and after treatment with CPAP decreased to 0.7 ± 0.3 voids per night (Guilleminault et al, 2004). A significant improvement in nocturia by treating OSA with CPAP also has been observed in women (Fitzgerald et al, 2006).

Because ADH is essential in controlling urinary concentration, it is not surprising that synthetic antidiuretics have been used to treat nocturia in addition to being standard replacement therapy for polyuric conditions such as central diabetes insipidus and primary nocturnal enuresis (PNE). Desmopressin (DDAVP) is a selective V₂-receptor agonist that retains the antidiuretic properties of vasopressin but lacks its unwanted pressor activity (Vilhardt, 1990). **When bound to V₂ receptors in the renal collecting tubules, desmopressin increases water permeability, enhances water reabsorption, dilutes extracellular fluid, and concentrates urine (Hammer and Vilhardt, 1985).** There have been multiple clinical trials of nocturia patients treated with desmopressin (Table 78-3). Desmopressin currently has the following recommendations for the treatment of nocturia:

- ICI: Grade A (level 1 evidence) (Andersson et al, 2013)
- European Association of Urology (EAU): Grade A (level 1b evidence) (Gravas et al, 2015)

For maximum concentration of urine, large amounts of urea must be deposited in the interstitium of the inner renal medulla. V₂ receptor activation (e.g., by DDAVP) increases urea permeability by 400% in the terminal portions of the inner medullary collecting duct by activating an AVP-regulated urea transporter, most likely by means of PKA-induced phosphorylation

From Friedman FM, Weiss JP. Desmopressin in the treatment of nocturia: clinical evidence and experience. Ther Adv Urol 2013;5:310-7.

(Sands, 2003). Desmopressin tablet studies have shown long-term reduction in nocturnal voids compared to baseline in both men (48% to 58%) and women (55% to 59%) (Lose et al, 2004) while increasing the initial sleep period by 2 hours in both (Mattiasson et al, 2002; Lose et al, 2003). Hyponatremia is a well-known undesired effect of desmopressin. In high-dose desmopressin tablet studies, 4.9% of all patients developed hyponatremia (defined as serum sodium <130 mmol/L). Patients with hyponatremia were older, smaller, and moderately more polyuric and had slightly lower basal serum sodium level and moderately lower creatinine clearance rate than those without hyponatremia. Nearly all patients who developed hyponatremia in the tablet studies were 65 years of age or older (Rembratt et al, 2006). More recently, studies have been completed with the intraorally dispersible preparation of desmopressin ("melt"). Melt was found to decrease overall nocturia severity and to increase the 33% responder rate. In a 4-week randomized, double-blind study, 757 patients who reported three or more voids per night (90% of whom had nocturnal polyuria) received 10, 25, 50, or 100 µg of melt or placebo. Those who received placebo, 10, 25, 50, or 100 µg of melt had the following reduction in number of nocturnal voids from baseline respectively: -0.86, -0.83, -1.00, -1.18*, and -1.43* and had the following percent increase in 33% responder rate: 47%, 47%, 50%, 53%, 71%* (Weiss et al, 2012). In both men at 50 µg and women at 25 µg desmopressin melt, the odds of increasing the first uninterrupted sleep period to 4 hours or longer was significantly greater than placebo at 1 week and after months 1, 2, and 3 ($P < .0001$) (Sand et al., 2013; Weiss et al, 2013b). In a follow-up study designed to investigate the lowest possible therapeutically effective dose of desmopressin, the efficacy and safety of desmopressin orally disintegrating tablets (ODT) 50 µg and 75 µg in men with nocturia (two or more nocturnal voids) was investigated. In men treated with 50 µg of desmopressin, there was a -0.37 difference in reduction of nightly voids versus placebo ($P = .0003$). In men treated with 75 µg of desmopressin, there was a -0.41 difference in reduction of nightly voids versus placebo ($P < .0001$). In those treated with 50 µg, 0% had serum sodium from 126 mmol/L to 129 mmol/L and 2% had serum sodium less than 125 mmol/L. In those treated with 75 µg, 4% had serum sodium from 126 mmol/L to 129 mmol/L and 3% had serum sodium less than 125 mmol/L (Weiss et al, 2013b). From these data it could be concluded that 50 µg of desmopressin melt may be the lowest therapeutically beneficial dose for men. In a related study, 261 women (age range 19 to 87 years) with an average of three voids per night were given 25 µg desmopressin ODT. Desmopressin ODT reduced nocturia by -1.46 (treatment difference vs. placebo: -0.22; $P = .028$) and increased odds of a 33% or greater response (from baseline nocturia severity) versus placebo by 85% (OR 1.85; $P = .006$) at month 3. This low dose of desmopressin melt increased mean time to first nocturnal void by 155 minutes (treatment difference vs. placebo: 49 min; $P = .003$) and reduced NUV by 235 mL (treatment difference vs. placebo: 83 mL; $P = .003$) at month 3. There were no serum sodium drops less than 125 mmol/L or treatment withdrawals as a result of hyponatremia (Sand et al, 2013).

Women appear to be more sensitive (by a factor of at least 2) to desmopressin than men in terms of effects on nocturnal urine production (Juul et al, 2011) and duration of action (Yamaguchi et al, 2013). This may be because the gene for the V_2 receptor is located on the X chromosome. It is hypothesized that the gene for V_2 can escape inactivation that results in a higher density of V_2 receptors in women and thus a greater response to desmopressin. The phenomenon of gender differential sensitivity to desmopressin may explain why women seem to fare as well with a lower dose of the melt preparation than men (25 µg vs. 50 µg minimum effective dosages, respectively, based on the most recent studies as described herein).

Bae and colleagues (2013) demonstrated that desmopressin is a useful treatment in men with nocturia refractory to treatment with α -blockers. There were 216 patients enrolled in this study (76% with nocturnal polyuria, 7.2% with decreased nocturnal bladder capacity, and 16.8% with mixed cause). The number of nocturnal voids decreased from a mean of 7.0 to 5.7 episodes for 3 days at the 24-week visit (Bae et al, 2013).

In summary, when considering the use of desmopressin to treat nocturia, voiding diary analysis should immediately follow a standard urologic history and physical examination. Patients found to have global polyuria should be excluded for further evaluation. Patients with low volumes per void and no nocturnal polyuria may need nonantidiuretic treatment approaches. **Current thinking is that desmopressin would be most appropriate therapy for patients with nocturia related to nocturnal polyuria.** There is a gender sensitivity differential between genders (men appear to require a higher dose than women). Even though the risk for hyponatremia is less than 1% in those younger than 65 and 8% in those older than 65 years of age, it is always wise to obtain a baseline serum sodium before commencing therapy. Desmopressin should not be given to elderly patients (younger than 65 years of age) with baseline hyponatremia. It is advisable to monitor the serum sodium within 7 days and then 28 days after initial or incremental dosing, then continuing to check sodium levels every 6 months or more often as indicated. Table 78-4 presents a complete summary of medications used to treat nocturnal polyuria, including desmopressin.

Diminished Global and Nocturnal Bladder Capacity

Cause

Diminished bladder capacity has many causes, including infra-vesical obstruction, idiopathic nocturnal detrusor overactivity (NDO), neurogenic bladder, cystitis (bacterial, interstitial, tuberculous, radiation), and cancer of the bladder, prostate, or urethra. NDO occurs in association with nocturia in most patients with detrusor overactivity plus overactive bladder (OAB). NDO does not normally occur during sleep, is not due to sleep disturbance, and is not linked to nocturnal polyuria (Krystal et al, 2010). Additional causes of low global or nocturnal bladder capacity include learned voiding dysfunction, anxiety disorders, bladder calculi, ureteral calculi, and drugs such as xanthines (caffeine, theophylline) and β -blockers (Weiss, 2012). Low bladder compliance is also a risk factor for nocturia severity (Tsui et al, 2013).

Management

Treating bladder outlet obstruction (BOO) is thought to improve nocturia by lowering postvoid residual (PVR) volume, increasing functional bladder capacity, and reducing urinary frequency. Reducing BOO also diminishes input from afferents in the bladder neck and the prostatic urethra (Cumming and Chisholm, 1992; Margel et al, 2007; Housami and Abrams, 2008). Tamsulosin therapy and transurethral resection of prostate (TURP) significantly reduced the number of episodes of nocturia in 17.9% and 32.2% of patients, respectively (Yoshimura et al, 2003), and by an average of 1.3 episodes per night in patients treated with TURP (Antunes et al, 2009). Outlet reduction also may act by increasing hours of uninterrupted sleep, with commensurate benefit to nocturia-specific quality of life. In patients who underwent simple prostatectomy, nocturia episodes decreased from a baseline of 3.4 to 2.6, 2 to 3 months postoperatively ($P < .001$) and hours of uninterrupted sleep increased from 1.83 at baseline to 2.74, 2 to 3 months postoperatively ($P < .001$) (Margel et al, 2007). In a retrospective analysis of 1258 men, improvement in nocturia-related quality of life was studied after various forms of treatment for BPH, including watchful waiting, α -blockers, TURP, and transurethral microwave treatment (TUMT). After 6 to 12 months, watchful waiting, α -blockers, TURP, and TUMT yielded reduction in nocturia episodes by 7%, 17%, 75%, and 32%, respectively. Improvements in nocturia-related quality of life were most strongly associated with

* $P < .05$.

TABLE 78-4 Summary of Pharmacotherapeutic Agents Used to Treat Nocturnal Polyuria

DRUG NAME	DOSE	SIDE EFFECT(S)	CONTRAINDICATION(S)
Furosemide*	40 mg PO 6 hr before sleep (Dose range 20-80 mg PO in adults. The study mentioned in this text used only 40 mg in the context of nocturia.)	Anorexia Nausea/vomiting Constipation Cramping Diarrhea Blurred vision Hearing loss Tinnitus Headaches Orthostatic hypotension Hypokalemia Dehydration Metabolic alkalosis Muscle cramps SLE exacerbation	Hypersensitivity Anuria Hepatic coma Hypovolemia Severe hypokalemia
Imipramine*	20 mg PO qhs	Prolong the PR interval Prolong QRS interval Prolong QTc interval Increase the heart rate Lower T-wave amplitude Torsades de pointes Sudden death	Hypersensitivity Usage of MAOI within 14 days Acute recovery period after MI
Desmopressin*	Intranasal: 10 µg/spray; max 40 µg/day (central DI indication only) Oral: 0.1-mg tablets; max 0.6 mg/day for PNE Melt: 60-, 120-, 240-µg melt tabs Melt "low dose": 25 µg (women) and 50-100 µg (men)	Water intoxication Hyponatremia Flushing Vulval pain Diarrhea Mild abdominal cramps Nausea Increased SGOT Thrombosis Cough Dyspnea Drowsiness Dizziness Headache Abnormal thinking Seizures	Hypersensitivity CrCl <50 mL/min Hyponatremia History of hyponatremia Von Willebrand disease, type IIB

CrCl, creatine clearance; DI, diabetes insipidus; MAOI, monoamine oxidase inhibitor; MI, myocardial infarction; PNE, primary nocturnal enuresis; SGOT, serum glutamic oxaloacetic transaminase; SLE, systemic lupus erythematosus.

treatment-associated declines in nocturia severity (van Dijk et al, 2010). Other reports point out that nocturia still persists despite bladder outlet-reducing surgery. The NHANES III in the United States showed that among those who undergo TURP, nocturia (two or more voids per night) persists for 41% of people 60 to 69 years of age and 50% of those 70 years or older (Platz et al, 2002).

TURP appears to be superior to tamsulosin for treatment of BPH-related nocturia. In a single-center study, 66 men with LUTS (mean age 68.9 years) were randomized to receive **TURP or tamsulosin 0.4 mg orally at bedtime** for management of nocturia. Nocturia severity was assessed at baseline, 3 months, and 1 year. TURP was associated with a significant improvement compared to tamsulosin in the number of nocturnal awakenings, IPSS, International Consultation on Incontinence Questionnaire Nocturia (ICIQ-N), and ICIQ-N Quality of Life (N-QoL) scores. Hours of uninterrupted sleep increased in both groups but were not statistically different (Simaioridis et al, 2011).

A secondary analysis of the Department of Veterans Affairs Cooperative Study Trial studied the changes in nocturia in a cohort of 1078 men with BPH who were randomly assigned to receive **terazosin, finasteride, combination, or placebo**. Overall, episodes of nocturia decreased from a baseline mean of 2.5 to 1.8, 2.1, 2.0, and 2.1 episodes in the terazosin, finasteride, combination, and placebo groups, respectively. Mean reduction of nocturia episodes from treatment with terazosin alone was significantly different from that with treatment with combination therapy ($P = .03$), finasteride ($P = .0001$), and placebo ($P = .0001$). Terazosin and combination therapy reduced the number of nocturia episodes in men with BPH, although the advantage of terazosin over placebo was only a net reduction of 0.3 episode (Johnson et al, 2003).

Using as a model the "typical" patient with OAB who has 12 voids per day, one to four episodes of arising from sleep to void, and 50% of the voids occurring with urgency, an effective antimuscarinic would be expected to reduce the episodes of urgency by half

of 50%, or 25%. This would amount to a reduction in nocturia from 4 to 3, 3 to 2.25, and 2 to 1.5. Clearly the benefit would be most appreciated by those more severely afflicted with nocturia, if the theory is correct. In a subgroup analysis of 962 patients of both sexes older than 20 years of age with OAB studied for response to solifenacin 5 mg and 10 mg, solifenacin 10 mg decreased nocturia “significantly” by 0.12 episodes and increased volume per nocturnal micturition by 28 mL. Hence, the clinical outcomes appear to be ineffective (Yokoyama et al, 2011).

In a 12-week randomized, controlled study, 850 patients were given 4 mg **tolterodine extended release** (Tolt ER) or placebo once daily 4 hours before going to bed. All subjects had eight or more micturitions per 24 hours with or without urge incontinence and nocturia (mean of 2.5 episodes per night). Tolt ER did not significantly reduce the total number of nocturnal micturitions; however, it did significantly reduce OAB-related and severe OAB-related nocturnal micturitions versus placebo. Tolt ER did not affect non-OAB nocturnal micturitions (Rackley et al, 2006). The suggestion here was that antimuscarinic therapy would benefit nocturic voids that are characterized by severe urgency.

A randomized, controlled trial of 658 patients at 52 sites were given either placebo or **tropium chloride** 20 mg twice daily in this 12-week, multicenter, parallel, double-blind, placebo-controlled study. After 12 weeks a significant decrease was found in the mean number of nocturic episodes per night: 0.29 episode for placebo versus 0.57 episode for drug (baseline was two episodes per night) (Rudy et al, 2006).

Fesoterodine significantly improved all diary end points compared with placebo except for nocturnal voids and nocturnal urgency episodes (Nitti et al, 2007; Dmochowski et al, 2010; Herschorn et al, 2010). However, in a study powered to determine the effect of fesoterodine on nocturnal urgency as a primary end point, **fesoterodine** did decrease the number of nocturnal urgency episodes and the number of nocturnal voids when compared to placebo. This particular study looked at change from baseline to week 12 in the number of nocturnal urgency episodes per 24 hours. Urgency was defined as an intense and/or sudden need to urinate. The subject rated the feeling of urgency associated with each micturition episode using the 5-point Urinary Sensation Scale (USS) (Coyne et al, 2011), where 1 = no feeling of urgency and 5 = unable to hold and leaked urine. Nocturnal urgency episodes were defined as those with a USS rating of 3 or greater. The mean reduction from baseline to week 12 in nocturnal urgency episodes per 24 hours was statistically significantly greater with fesoterodine than placebo (−1.29 vs. −1.06, $P = .0030$). Mean reduction from baseline to week 12 in nocturnal micturitions per 24 hours was significantly greater with fesoterodine than placebo (−1.02 vs. −0.84, $P = .0112$) (Weiss et al, 2013a).

A prospective randomized trial was conducted with 2583 men with one or more episodes of nocturia at baseline who were treated with doxazosin, finasteride, combination therapy (doxazosin + finasteride), or placebo. Treatment effectiveness was measured by a self-reported number of nocturia episodes at 1 and 4 years after treatment. After 1 year, mean nocturia was reduced by 0.35, 0.40, 0.54, and 0.58 in the placebo, finasteride, doxazosin, and combination groups, respectively; reductions with combination therapy and with doxazosin were statistically greater than with placebo ($P < .05$). After 4 years, the number of nocturia episodes was also significantly reduced in patients treated with doxazosin and combination therapy versus placebo ($P < .05$). In a subgroup of men older than 70 years of age ($n = 495$), all of the drugs significantly reduced nocturia at 1 year (finasteride 0.29, doxazosin 0.46, and combination 0.42) compared to placebo (0.11, $P < .05$). This study confirmed that α -blockers alone are as effective as α -blockers in combination with 5 α -reductase inhibitors (5-ARIs) for treatment of nocturia (Johnson et al, 2007).

A randomized, double-blind, placebo-controlled study was carried out in which patients were assigned to one of four groups for 12 weeks: placebo ($n = 222$), 4 mg Tolt ER ($n = 217$), 0.4 mg tamsulosin ($n = 215$), and combination Tolt ER + tamsulosin ($n = 225$). The combination of Tolt ER + tamsulosin significantly reduced

the number of micturitions per night versus placebo (−0.59 vs. −0.39, $P = .02$) (Kaplan et al, 2006).

In conclusion, α -blockers, 5-ARIs, antimuscarinics, and antimuscarinics plus α -blockers have occasionally been found to have a statistically significant reduction in nocturia episodes, but clinical significance appears to be minimal. When 5-ARIs and α -blockers are used in combination, they have the same degree of success as α -blockers alone. The optimal patients to treat with medications that target the bladder and the prostate appear to be those who have a large number of nocturia episodes (mostly resulting from severe urgency).

There have also been various alternative treatments for nocturia, including cyclooxygenase-2 inhibitors combined with α -blockers (Gorgel et al, 2013), sedatives (Song and Ku, 2007; Sugaya et al, 2007), melatonin (Drake et al, 2004; Sugaya et al, 2007), and phytotherapy. A systematic review of 1562 men from 18 randomized control trials examined the effect of *Pygeum africanum* on various BPH symptoms, including nocturia. There was no comparison of *P. africanum* to other pharmacologic treatments for BPH, including α -blockers and 5-ARIs. Compared to men taking placebo, those taking *P. africanum* reported a 19% reduction in nocturia (weighted mean difference [WMD] of −0.9 times per evening, $P > .05$) (Wilt and Ishani, 1998).

Another phytotherapeutic, Cernilton, is prepared from the ryegrass pollen *Secale cereale*. A systematic review was conducted to assess the efficacy of Cernilton on urinary symptoms in men with BPH. Cernilton reduced nocturia compared with placebo and another neutraceutical, Paraprost. Versus placebo, the weighted risk ratio for improvement of nocturia was 2.05 (95% CI = 1.41 to 3.00); thus those taking Cernilton were approximately two times more likely to have their nocturia improve over those taking placebo. Versus Paraprost, the WMD was −0.40 nocturic episodes per evening (95% CI = −0.73 to −0.07). Data were collected from a self-rated urinary symptom survey. The limitations of these trials were short duration, limited number of enrollees, gaps in reported outcomes, quality control of preparations, and lack of a proved active control (Wilt et al, 2011).

Mirabegron, a β_3 -adrenergic agonist approved by the U.S. Food and Drug Administration to treat OAB, showed an improvement in nocturia measured by the OAB symptom score at 3 and 6 months after beginning treatment in female patients over 70 years of age who did not respond to anticholinergics (Nakanishi, 2013). For a complete list of medications used to treat diminished global or nocturnal bladder capacity, including mirabegron, see Table 78-5.

Mixed Nocturnal Polyuria and Diminished Global and Nocturnal Bladder Capacity

In a review of 194 consecutive patients with nocturia, 13 (7%) had nocturnal polyuria (NPi >0.35), 111 (57%) had decreased nocturnal bladder capacity, and 70 (36%) had “mixed” cause. Forty-five (23%) also had polyuria (defined as 24-hour urine output >2500 mL). Nocturnal polyuria was a significant component of nocturia in 43% of the patients. Thus the cause of nocturia was found to be multifactorial and often unrelated to an underlying urologic condition (Weiss et al, 1998). In a U.S. veteran population of men 50 years of age and older, Vaughan and colleagues (2009) demonstrated a significant improvement in ANV ($P < .001$), bother ($P < .001$), time to initiating sleep ($P = .003$), time to return to sleep ($P = .03$), and quality of sleep ($P < .001$) after single or combined pharmacotherapy and/or behavioral modification to address the mixed etiologic category of nocturia. Behavioral modification included reduced caffeine and alcohol intake, limited nighttime fluid intake, and improved sleep hygiene through moderate exercise and attention to room temperature, noise, and lighting. Additional interventions included early evening leg elevation and compression stockings if patients had bilateral lower extremity edema. Also, if patients had BPH-related symptoms (American Urology Association symptom score ≥ 8 , maximum uroflow [Qmax] 4 to 15 mL/sec), terazosin was titrated as tolerated/needed to 10 mg daily. If

LA, long-acting; UTI, urinary tract infection.

patients reported eight or more voids in 24 hours, Tolt ER 2 mg to 4 mg daily was initiated. If return to sleep required 30 minutes or more after an awakening, zaleplon 5 mg nightly after the first nocturia episode between 11:00 PM and 3:00 AM was recommended. This proved to be a structured, multimodal approach with little risk (one trip to an emergency room for hypotension after taking terazosin) (Vaughan et al, 2009). Multicomponent treatment was further found to be an effective strategy to treat nocturia in a study

by Johnson and coworkers (2013) in which men on α -blockers received individually titrated drug therapy (extended-release oxybutynin) or multicomponent behavioral treatment (pelvic floor muscle training and delayed voiding and urge suppression techniques). Participants with two or more episodes of nocturia at baseline showed larger changes with behavioral treatment compared with antimuscarinic therapy (mean reduction = 1.26 vs. 0.61, respectively; $P = .008$).

Polyuria

Etiology

Polyuria is defined as 24-hour urine output greater than 40 mL/kg. Once a steady state is reached, polyuria is associated with excessive oral intake of fluids (polydipsia). This results in urinary frequency both day and night because of the global overproduction of urine in excess of bladder capacity. Nocturia is often the manifesting symptom of patients with polyuria of any cause. Hence, it behooves the urologist to understand both its cause and diagnostic measures to sort out its various causes. Common underpinnings of polyuria include diabetes mellitus, diabetes insipidus, and primary polydipsia (dipsogenic and psychogenic).

Diabetes insipidus is a disorder of water balance in which inappropriate excretion of water leads to polydipsia in an effort to prevent circulatory collapse. Diabetes insipidus can be central or nephrogenic. Central diabetes insipidus occurs when there is a deficiency in the synthesis or secretion of endogenous ADH. This can be due to loss of neurosecretory neurons in the hypothalamus or the posterior pituitary gland as a result of trauma, primary pituitary tumors (e.g., craniopharyngioma), metastatic disease (e.g., breast, lung), infiltrative diseases (e.g., sarcoid), infarction (e.g., Sheehan syndrome postpartum), or infection (e.g., tuberculosis, meningitis) or can be idiopathic (Shapiro and Weiss, 2012). Nephrogenic diabetes insipidus is diuresis in the setting of normal ADH secretion, but the kidneys do not respond appropriately to the hormone, as in some patients with chronic kidney disease. Some extrarenal causes of diabetes insipidus include PGE₂, ANP, hypercalcemia, hypokalemia, lithium, and tetracyclines. This mechanism may explain how nonsteroidal anti-inflammatory drugs can improve nocturia, because of the effect of these drugs in blocking PGE₂-mediated diuresis (Araki et al, 2004).

The diagnostic algorithm for polyuria begins with an overnight water deprivation test (OWDT). To perform an OWDT, the patient is told not to drink anything during the night. It is normal if the first morning urine osmolality is greater than 800 mOsm/kg H₂O. Normal implies that there is an appropriate secretion of ADH and an appropriate renal response. If the OWDT is normal, polyuria is due to primary polydipsia (neurogenic or dipsogenic). If the OWDT is abnormal, the patient has diabetes insipidus. To distinguish central from nephrogenic diabetes insipidus, a renal concentrating capacity test (RCCT) may be performed. The RCCT is performed by giving 40 µg of desmopressin intranasally or 0.4 mg orally. The patient's bladder is emptied and urine osmolality is tested 3 to 5 hours later. Water is restricted for the first 12 hours after the drug is administered. The RCCT is normal if the urine osmolality rises to at least 800 mOsm/kg H₂O (Weiss, 2012). If the RCCT is normal, the patient has central diabetes insipidus and can be treated with desmopressin replacement therapy. If the RCCT is abnormal, the patient has nephrogenic diabetes insipidus, which has no specific treatment.

Management

Patients who have a 24-hour urine production greater than 30 mL/kg may benefit from water restriction during the day and night. Tani and associates (2014) showed that adjusting water and food intake so that 24-hour urine production is less than 30 mL/kg reduced NUV and nocturnal urinary frequency with no adverse events. This illustrates that guidance on water intake may be a safe and effective conservative lifestyle management strategy.

A patient with **primary (dipsogenic or psychogenic) polydipsia** will have normal urine osmolality on water deprivation tests. **Dipsogenic polydipsia** is associated with a history of a central neurologic abnormality such as a history of brain trauma

or radiation. Psychogenic polydipsia is a long-term behavioral or psychiatric disorder. It is important to identify the cause of a patient's polyuria to treat it effectively. For example, if a patient with polyuria has diabetes mellitus, controlling glycosuria may improve the polyuria. Central diabetes insipidus may be treated with synthetic vasopressin analogues. Patients without diabetes insipidus who are found to have polydipsia and are compulsive water drinkers may benefit from psychotherapy (Weiss, 2012). Nocturia as a manifesting complaint is expected to benefit from appropriate therapy for polyuria.

KEY POINTS: EVALUATION AND MANAGEMENT OF NOCTURIA

- Classification of nocturia using a frequency-volume chart yields up to 17 different underlying medical conditions that may potentially contribute to its genesis.
- OSA is a common cause of nocturnal polyuria.
- The normal circadian pattern of nocturnal urine production is age dependent.
- Treating nocturnal polyuria should focus on underlying contributing medical comorbidities.
- There are many causes of diminished bladder capacity, including infravesical obstruction, idiopathic nocturnal detrusor overactivity, neurogenic bladder, cystitis (bacterial, interstitial, tuberculous, radiation), and cancer of the bladder, prostate, or urethra.
- Treating BOO is thought to improve nocturia by lowering PVR volume, increasing functional bladder capacity, and reducing urinary frequency.
- α -Blockers, 5-ARIs, antimuscarinics, and antimuscarinics plus α -blockers have been found to have a statistically but questionably clinically significant reduction in nocturia episodes.
- When 5-ARIs and α -blockers are used in combination, they have the same degree of success as α -blockers alone.
- The optimal group to treat with medications that target the bladder and the prostate appear to be those who have a large number of nocturia episodes (mostly as a response to severe urgency) and not from nocturnal polyuria.
- Polyuria is defined as 24-hour urine output greater than 40 mL/kg and thus must be diagnosed through use of frequency-volume charts. Treatment of conditions underlying polyuria should benefit nocturia.
- Patients with nocturnal polyuria unrelated to specific causes such as peripheral edema or sleep apnea may benefit from treatment with desmopressin.
- Desmopressin should be avoided in elderly patients (older than 65 years of age) and those with baseline hyponatremia.

Pharmacologic Therapy to Facilitate Bladder Filling and Urine Storage

The function of the lower urinary tract (LUT) is to effect efficient and low-pressure bladder filling, low-pressure urine storage with normal sensation and perfect continence, and periodic complete voluntary emptying, again at low pressure. The structures involved include the smooth musculature of the bladder and the bladder outlet, and striated muscle, both intrinsic (to the bladder outlet) and extrinsic (the striated musculature surrounding the bladder outlet and the striated musculature of the pelvic floor). These component structures are controlled by a complex interplay among the central and peripheral nervous systems and local regulatory factors. **Pharmacologic alteration of LUT function can occur at any point along the afferent or efferent limb of this complex neuromuscular cascade, by receptor activation or stimulation or blockade, by affecting the concentration of neurotransmitter at an activation site, or by stimulating or inhibiting signal transduction mechanisms** (Andersson and Wein, 2004; Andersson et al, 2009; Birder et al, 2009; Fry et al, 2009; Andersson et al, 2013a; see also Chapter 69).

This chapter considers the pharmacologic management of bladder filling and storage and bladder emptying and voiding dysfunction. The conceptual basis of the organization is that of the expanded functional classification shown in Boxes 70-1 and 70-2 in Chapter 70 and the division of therapies in the relatively simple manner of those that facilitate urine storage and bladder filling and those that facilitate bladder emptying and voiding (see Boxes 70-3 and 70-4 in Chapter 70). Although the principles expressed are generally applicable to patients of all ages, specifics concerning usage in the pediatric age groups and in the elderly are considered in detail in Chapters 142 and 143. Specific information regarding the pharmacologic management of LUT dysfunction secondary to obstruction by benign prostatic enlargement (BPE) is considered in detail in Chapter 104, whereas drug therapy for the treatment of bladder and pelvic pain disorders is considered in detail in Chapters 13 and 14.

As an apology in explanation to significant contributors to the field whose works have not been specifically referenced by name as frequently as they could have been, please note that the citations have been chosen primarily because of their comprehensive review or specific informational content and not because of originality or initial publication on a particular subject, except where noted.

PHARMACOLOGIC THERAPY TO FACILITATE BLADDER FILLING AND URINE STORAGE

Inhibiting Bladder Contractility, Decreasing Sensory Input, Increasing Bladder Capacity

Bladder Contraction and Muscarinic Receptors

The major portion of the neurohumoral stimulus for physiologic bladder contraction is acetylcholine (ACh)-induced stimulation of

Pharmacologic Therapy to Facilitate Bladder Emptying

postganglionic parasympathetic muscarinic cholinergic receptor sites in the bladder (detrusor smooth muscle and possibly other sites) (see Chapter 69). **Atropine and atropine-like agents will depress normal bladder contractions and involuntary bladder contractions (detrusor overactivity [DO]) of any cause** (Andersson, 1988, 1993; Andersson and Wein, 2004). **In patients with involuntary contractions, the volume to the first DO will usually be increased, the amplitude of the contraction decreased, and the total bladder capacity increased** (Jensen, 1981).

It has been stated that bladder compliance in normal individuals and in those with neurogenic detrusor overactivity (NDO) (Abrams et al, 2002), in whom the initial slope of the filling curve on cystometry is normal before the involuntary contraction, does not seem to be significantly altered by antimuscarinic agents and that the effect of pure antimuscarinics in patients who exhibit only decreased compliance had not been well studied. Regarding the subject of bladder tone during filling, Andersson (1999a, 1999b, 2004, 2011b) and Andersson and Yoshida (2003) have pointed out that although it is widely accepted that there is normally no sacral parasympathetic outflow to the bladder during filling, antimuscarinic drugs increase, and anticholinesterase inhibitors decrease, bladder capacity. **Because antimuscarinic drugs do seem to affect the sensation of urgency during filling, this suggests an ongoing ACh-mediated stimulation of detrusor tone** (see later). If this is correct, agents that inhibit ACh release or activity would be expected to contribute to bladder relaxation or the maintenance of low bladder tone during filling with a consequent decrease in filling and storage symptomatology unrelated to the occurrence of DO. **Outlet resistance, at least as reflected by urethral pressure measurements, does not seem to be clinically affected.**

Although the antimuscarinic agents usually produce significant clinical improvement in patients with DO and associated symptoms, they typically produce only partial inhibition. In many animal models, atropine only partially antagonizes the response of the whole bladder to pelvic nerve stimulation and of bladder strips to field stimulation, although it does completely inhibit the response of bladder smooth muscle to exogenous cholinergic stimulation. This phenomenon, which is called *atropine resistance*, is secondary to release of a transmitter other than ACh (see Andersson, 1993; Andersson et al, 1999; Andersson and Wein, 2004; see also Chapter 69). Atropine resistance is the most common hypothesis invoked to explain the clinical difficulty in eradicating DO with antimuscarinic agents alone, and it is also invoked to support the rationale of combined treatment of DO with agents that have different mechanisms of action (Andersson, 2006).

Andersson and Wein (2004) cite references stating that atropine resistance seems to be of little importance in normal human bladder muscle, but point out that atropine-resistant (nonadrenergic, noncholinergic [NANC]) contractions have been reported in human detrusor smooth muscle and in morphologically and/or functionally changed bladders in individuals with various types

of voiding dysfunction. Thus, the importance or unimportance of an atropine-resistant component to detrusor contraction in the treatment of DO in humans remains to be established.

Muscarinic Receptors

In the human bladder, where the mRNAs for all the five pharmacologically defined muscarinic receptors, M_1 to M_5 , have been demonstrated (Sigala et al, 2002; Abrams et al, 2006a; Giglio and Tobin, 2009; Andersson, 2011a), there is a predominance of mRNAs encoding M_2 and M_3 receptors (Yamaguchi et al, 1996; Sigala et al, 2002; Abrams et al, 2006a; Giglio and Tobin, 2009; Andersson, 2011a). This seems to be the case also in the animal species investigated (Hegde and Eglén, 1999; Chess-Williams, 2002; Andersson and Arner, 2004). Both M_2 and M_3 receptors can be found on detrusor muscle cells, where M_2 receptors predominate at least 3:1 over M_3 receptors, but also in other bladder structures, which may be of importance for detrusor activation. Thus, muscarinic receptors can be found on urothelial cells, on suburothelial nerves, and on other suburothelial structures, such as interstitial cells (Chess-Williams, 2002; Gillespie et al, 2003; Gillespie, 2004; Mansfield et al, 2005; Bschiepfer et al, 2007; Giglio and Tobin, 2009; Andersson, 2011a).

In human as well as animal detrusor, the M_3 receptors are believed to be the most important for contraction (Andersson, 1993; Chess-Williams, 2002; Abrams et al, 2006a; Giglio and Tobin, 2009; Andersson, 2011a). No differences between genders could be demonstrated in rat and human bladders (Kories et al, 2003). The functional role for the M_2 receptors has not been clarified, and even in M_3 receptor knockout (KO) mice they seem responsible for less than 5% of the carbachol-mediated detrusor contraction (Matsui et al, 2000). Stimulation of M_2 receptors has been shown to oppose sympathetically (β -adrenoceptor [β -AR]) mediated smooth muscle relaxation (Hegde et al, 1997). However, based on animal experiments, M_2 receptors have been suggested to directly contribute to contraction of the bladder in certain disease states (denervation, outflow obstruction). Experiments on human detrusor muscle by Stevens and coworkers (2007) could not confirm this, however. Pontari and colleagues (2004) analyzed bladder muscle specimens from patients with neurogenic bladder dysfunction to determine whether the muscarinic receptor subtype mediating contraction shifts from M_3 to the M_2 receptor subtype, as found in the denervated, hypertrophied rat bladder. They concluded that normal detrusor contraction is mediated by the M_3 receptor subtype, whereas contractions can be mediated by the M_2 receptors in patients with neurogenic bladder dysfunction.

Muscarinic receptors are coupled to G proteins, but the signal transduction systems may vary. In general, M_1 , M_3 , and M_5 receptors are considered to couple preferentially to $G_{q/11}$, activating phosphoinositide hydrolysis, in turn leading to activation of intracellular calcium. M_2 and M_4 receptors couple to pertussis toxin-sensitive $G_{i/o}$, resulting in inhibition of adenylate cyclase activity. In the human detrusor, Schneider and colleagues (2004a), confirming that the muscarinic receptor subtype mediating carbachol-induced contraction is the M_3 receptor, also demonstrated that the phospholipase C inhibitor U-73122 did not significantly affect carbachol-stimulated bladder contraction, despite blocking inositol trisphosphate (IP_3) generation. They concluded that carbachol-induced contraction of human urinary bladder is mediated via M_3 receptors and largely depends on Ca^{2+} entry through nifedipine-sensitive channels and activation of the Rho-kinase pathway. Thus, it may be that the main pathways for muscarinic-receptor activation of the detrusor via M_3 receptors are calcium influx via L-type calcium channels, and increased sensitivity to calcium of the contractile machinery via inhibition of myosin light chain phosphatase through activation of Rho-kinase.

The signaling mechanisms for the M_2 receptors are less clear than those for M_3 receptors. As mentioned previously, M_2 receptor stimulation may oppose sympathetically induced smooth muscle relaxation, mediated by β -ARs via inhibition of adenylyl cyclase

(Hegde et al, 1997). In agreement with this, Matsui and colleagues (2003) suggested, based on results obtained in M_2 receptor KO mice, that a component of the contractile response to muscarinic agonists in smooth muscle involves an M_2 receptor-mediated inhibition of the relaxant effects of agents that increase cyclic adenosine monophosphate (cAMP) levels. M_2 -receptor stimulation can also activate nonspecific cation channels and inhibit K_{ATP} channels through activation of protein kinase C (Bonev and Nelson, 1993; Kotlikoff et al, 1999).

Muscarinic receptors may also be located on the presynaptic nerve terminals and participate in the regulation of transmitter release. The inhibitory prejunctional muscarinic receptors have been classified as muscarinic M_2 in the rabbit (Tobin and Sjögren, 1995) and rat (Somogyi and de Groat, 1992) and M_4 in the guinea pig (Alberts, 1995) and in the human bladder (D'Agostino et al, 2000). Prejunctional facilitatory muscarinic receptors appear to be of the M_1 subtype in the bladders of rat, rabbit (Somogyi and de Groat, 1992; Tobin and Sjögren, 1995), and humans (Somogyi and de Groat, 1999; Giglio and Tobin, 2009; Andersson, 2011b). The muscarinic facilitatory mechanism seems to be upregulated in overactive bladders (OABs) from chronic spinal cord-transected rats. The facilitation in these preparations is primarily mediated by M_3 muscarinic receptors (Somogyi and de Groat, 1999).

The relative roles of the different presynaptic and postsynaptic receptor subtypes in normal and abnormal bladder function still require clarification, and thus speculation regarding optimal drug therapy based only on in vitro receptor selectivity profiles represents, at the very least, a gross oversimplification of assumptions regarding the muscarinic regulation of bladder function. The muscarinic receptor functions may be changed in different urologic disorders, such as outflow obstruction, neurogenic bladders, DO without overt neurogenic cause, and diabetes (Andersson, 2000a, 2011b). However, it is not always clear what the changes mean in terms of changes in detrusor function.

In general, all drug therapy for LUT dysfunction is hindered by a concept that can be expressed in one word: *uroselectivity* (Andersson, 1998). The clinical usefulness of available antimuscarinic agents is limited by their lack of selectivity, responsible for the classic peripheral antimuscarinic side effects of dry mouth, constipation, blurred vision, and increase in heart rate (HR) and for the effects on cognitive functions (Table 79-1). Although M_3 -receptor selective agents have the potential to eliminate some of these side effects, it would appear that the M_3 receptors in tissues of the LUT are identical to those elsewhere in the body (Caulfield and Birdsall, 1998). It may be speculated, however, that there is some heterogeneity among M_3 receptors, and this has prompted many pharmaceutical companies to continue to search for the "ideal" antimuscarinic agent to treat DO, one that would be relatively selective for muscarinic receptors involved in the regulation of bladder contraction. Receptor selectivity, however, is not the only basis on which a drug may be uroselective. From a clinical standpoint, it would seem particularly important to be able to describe in relative terms the ratio between a drug dose required for a desired therapeutic action and the dose that produces side effects. A differential effect could be based not only on receptor selectivity but also on other known and as yet undefined physiologic, pharmacologic, or metabolic characteristics. Organ selectivity would thus seem to be the "holy grail" of such therapy. The same problematic set of concepts applies to virtually all drugs used for the treatment of LUT dysfunction.

Prevalence of Lower Urinary Tract Symptoms

The prevalence of lower urinary tract symptoms (LUTS), including OAB syndrome, varies with the criteria for diagnosis. According to Irwin and colleagues (2006), using the 2002 International Continence Society (ICS) definition, the overall prevalence of OAB was 11.8% (the EPIC study). The rates were similar in men and women and increased with age. A similar study by Herschorn and colleagues (2008) found the OAB prevalence to be 13% in Canadian men and 14% in women. Irwin and colleagues (2011)

TABLE 79-1 Muscarinic Receptors: Distribution and Function

REGION	SUBTYPE OF MUSCARINIC RECEPTOR	FUNCTION
Bladder	M ₂ > M ₃ (3:1)	M ₃ : mediates human detrusor contraction
Salivary glands, parotid gland	M ₁ , M ₃	M ₁ : high-viscosity lubrication M ₃ : salivation
Gastrointestinal tract	M ₂ > M ₃ (4:1)	M ₃ : stimulation of gastrointestinal motility
Brain	M ₁ to M ₅ (M ₃ sparse)	Involved in higher cognitive processes such as learning and memory (mostly M ₁)
Eye	M ₁ to M ₂ (M ₃ predominates)	Controls iris sphincter contraction
Heart	M ₂	Modulates pacemaker activity, atrioventricular conduction, and the force of contraction

Data from Abrams P, Andersson KE, Buccafusco JJ, et al. Muscarinic receptors: their distribution and function in body systems, and the implications for treating overactive bladder. *Br J Pharmacol* 2006;148:565–78.

estimated and predicted the worldwide and regional prevalence of LUTS, OAB, urinary incontinence (UI), and LUTS suggestive of bladder outlet obstruction (LUTS/BOO) in 2008, 2013, and 2018 based on current ICS symptom definitions in adults older than 20 years. An estimated 45.2%, 10.7%, 8.2%, and 21.5% of the 2008 worldwide population (4.3 billion) were affected by at least one LUTS, OAB, UI, and LUTS/BOO, respectively. By 2018, an estimated 2.3 billion individuals will be affected by at least one LUTS (18.4% increase), 546 million by OAB (20.1%), 423 million by UI (21.6%), and 1.1 billion by LUTS/ BOO (18.5%).

LUTS may be the result of several different mechanisms, both myogenic and neurologic (Morrison et al, 2002; Birder et al, 2009; Koelbl et al, 2009; Banakhar et al, 2012), and abundant drugs have been used for treatment. The 5th International Consultation on Incontinence (2013) assessed drugs used for treatment of incontinence (Andersson et al, 2013a). The assessment criteria (Table 79-2) were based on the Oxford guidelines, and the drugs included are listed in Tables 79-3 and 79-4.

Antimuscarinic (Anticholinergic) Agents

Mechanism of Action. For many years, antimuscarinic drugs have been the gold standard for treatment of OAB. Still, the ways by which they exert their beneficial effect have not yet been established.

ACh stimulates both muscarinic and nicotinic receptors (Abrams and Andersson, 2007). Antimuscarinics block selectively muscarinic receptors. They are currently the mainstay of treatment of OAB symptoms, even if new therapeutic options have been introduced (Andersson et al, 2013a). The **traditional view** is that in OAB and DO, the drugs act by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by ACh, released from activated cholinergic (parasympathetic) nerves. Thereby, they decrease the ability of the bladder to contract. **However, antimuscarinic drugs act mainly during the storage phase, decreasing urgency and increasing bladder capacity, and during this phase, there is normally no parasympathetic input to the LUT** (Morrison et al, 2002;

Andersson, 2004). Furthermore, antimuscarinics are usually competitive antagonists. This implies that when there is a massive release of ACh, as during micturition, the effects of the drugs should be decreased; otherwise the reduced ability of the detrusor to contract would eventually lead to urinary retention. Undeniably, high doses of antimuscarinics can produce urinary retention in humans, **but in the dose range used for beneficial effects in OAB and DO, there is little evidence for a significant reduction of the voiding contraction** (Finney et al, 2006) (Fig. 79-1). There is indirect clinical evidence for release of ACh during bladder filling in certain abnormal conditions. Smith and colleagues (1974) found that in patients with recent spinal cord injury (SCI), inhibition of ACh breakdown by use of cholinesterase inhibitors could increase resting tone and induce rhythmic contractions in the bladder. Yossepowitch and colleagues (2001) inhibited ACh breakdown with edrophonium in a series of patients with disturbed voiding or UI. They found a significant change in sensation and decreased bladder capacity, induction or amplification of involuntary detrusor contractions, or significantly decreased detrusor compliance in 78% of the patients with the symptom pattern of OAB, but in no patients without specific complaints suggesting DO. Thus, **during the storage phase, ACh may be released from both neuronal and non-neuronal sources** (e.g., the urothelium and suburothelium) and directly or indirectly (by increasing detrusor smooth muscle tone) excite afferent nerves in the suburothelium and within the detrusor. There is also good experimental evidence that antimuscarinics act during the storage phase by decreasing the activity in afferent nerves (both C and Aδ fibers) from the bladder (De Laet et al, 2006; Iijima et al, 2007).

Muscarinic receptors are found on bladder urothelial cells, where their density can be even higher than in detrusor muscle. The role of the urothelium in bladder activation has attracted much interest (Andersson, 2002a; de Groat, 2004; Birder and de Groat, 2007; Birder et al, 2009; Giglio and Tobin, 2009; Andersson, 2011b), but whether the muscarinic receptors on urothelial cells can influence micturition has not yet been established. Yoshida and colleagues (2004, 2006, 2008) found that there is basal ACh release in human bladder. This release was resistant to tetrodotoxin and much

diminished when the urothelium was removed; thus, the released ACh was probably of non-neuronal origin and at least partly generated by the urothelium. Thus during the storage phase, ACh and adenosine triphosphate (ATP) may be released from both neuronal and non-neuronal sources (e.g., the urothelium) and directly or indirectly (by increasing detrusor smooth muscle tone) excite afferent nerves in the suburothelium and within the detrusor. These mechanisms may be important in the pathophysiology of OAB and represent possible targets for antimuscarinic drugs.

Pharmacologic Properties. In general, antimuscarinics can be divided into tertiary and quaternary amines (Guay, 2003; Abrams and Andersson, 2007). They differ with regard to lipophilicity, molecular charge, and even molecular size, tertiary compounds typically having higher lipophilicity and molecular charge than quaternary agents. Atropine, darifenacin, fesoterodine (and its active metabolite 5-hydroxymethyl tolterodine [5-HMT]), imidafenacin, oxybutynin, propiverine, solifenacin, and tolterodine, are tertiary amines. They are generally well absorbed from the gastrointestinal tract and should theoretically be able to pass into the central nervous system (CNS), dependent on their individual

physicochemical properties. High lipophilicity, small molecular size, and less charge will increase the possibilities to pass the blood-brain barrier, but for some of the drugs this is counteracted by active transport out of the CNS by P-glycoprotein. Quaternary ammonium compounds, such as propantheline and trospium, are not well absorbed, pass into the CNS to a limited extent, and have a low incidence of CNS side effects (Guay, 2003). They still produce well-known peripheral antimuscarinic side effects, such as accommodation paralysis, constipation, increase in HR, and dryness of mouth.

Many antimuscarinics are metabolized by the P450 enzyme system to active and/or inactive metabolites (Guay, 2003). The most commonly involved P450 enzymes are CYP2D6 and CYP3A4. The metabolic conversion creates a risk for drug-drug interactions, resulting in either reduced (enzyme induction) or increased (enzyme inhibition, substrate competition) plasma concentration or effect of the antimuscarinic and/or interacting drug. Antimuscarinics secreted by the renal tubules (e.g., trospium) may theoretically be able to interfere with the elimination of other drugs using this mechanism.

**Figure 79-1.** Rationale for use of antimuscarinic agents in overactive bladder (OAB).

Antimuscarinics are still the most widely used treatment for urgency and urgency incontinence (Andersson, 2004; Andersson et al, 2009, 2013a). However, currently used drugs lack selectivity for the bladder, and effects on other organ systems may result in side effects that limit their usefulness. For example, all antimuscarinic drugs are contraindicated in untreated narrow-angle glaucoma.

One way of avoiding many of the antimuscarinic side effects is to administer the drugs intravesically. However, this is practical in only a limited number of patients.

Clinical Use. The clinical relevance of efficacy of antimuscarinic drugs relative to placebo has been questioned (Herbison et al, 2003). However, large meta-analyses of studies performed with the currently most widely used drugs (Chapple et al, 2005a, 2008a; Novara et al, 2008) clearly show that antimuscarinics are of significant clinical benefit. It was recommended that because the pharmacologic profiles of each drug (see later) and dosages differ, these factors should be considered in making treatment choices.

The durability of the effects of antimuscarinics is not known, and the relapse rate of symptoms after discontinuation of treatment has not been systematically studied. In 173 women with OAB symptoms for longer than 6 months, Lee and colleagues (2011) studied in a prospective, randomized, open-label trial what happened 3 months after the patients had been successfully treated for 1, 3, or 6 months. The relapse rate was 62%, and the request for re-treatment was 65%, indirectly suggesting an efficacy of treatment.

None of the antimuscarinic drugs in common clinical use (darifenacin, fesoterodine, imidafenacin, oxybutynin, propiverine, solifenacin, tolterodine, or trospium) is ideal as a first-line treatment for all OAB or DO patients. Optimal treatment should be individualized, implying that the patient's comorbidities and

concomitant medications, and the pharmacologic profiles of the different drugs, should be taken into consideration (Chapple et al, 2008a).

To compare the effects of different antimuscarinic drugs for OAB symptoms, Madhuvrata and colleagues (2012) analyzed 86 trials, 70 with parallel and 16 with crossover designs (31,249 adults), drawing attention to the significance of the adverse effect of dry mouth. They concluded that when the prescribing choice is between oral immediate-release (IR) oxybutynin or tolterodine, tolterodine might be preferred for reduced risk of dry mouth. Also, extended-release (ER) preparations of oxybutynin or tolterodine might be preferred to IR preparations because there is less risk of dry mouth. Comparing solifenacin and IR tolterodine, solifenacin might be preferred for better efficacy and less risk of dry mouth. Fesoterodine might be preferred over ER tolterodine for superior efficacy but has a higher risk of withdrawal because of adverse events in general, but in particular a higher risk of dry mouth.

Several studies have documented that the persistence with prescribed antimuscarinic therapy for OAB is low (Kelleher et al, 2005; Basra et al, 2008; Sears et al, 2010; Wagg et al, 2012). The most common causes seem to be lack of efficacy and adverse effects. However, there is some evidence suggesting that the tolerability of the different antimuscarinics may differ. Wagg and colleagues (2012) analyzed prescription data for patients receiving antimuscarinics for treatment of the OAB syndrome over a 12-month period. At 12 months, they found that the proportions of patients still on their original treatment were as follows: solifenacin, 35%; tolterodine ER, 28%; propiverine, 27%; oxybutynin ER, 26%; trospium, 26%; tolterodine IR, 24%; oxybutynin IR, 22%; darifenacin, 17%; and flavoxate, 14%. The longest mean persistence was reported for solifenacin (187 days vs. 77 to 157 days for the other treatments). Gomes and colleagues (2012) compared the persistence of oxybutynin or tolterodine therapy among older patients newly prescribed one of these drugs. This was a retrospective cohort study of Ontarians aged 66 years and older. Persistence with treatment was defined on the basis of refills for the drug within a grace period equal to 50% of the prescription duration. The authors identified 31,996 patients newly treated with oxybutynin and 24,855 newly treated with tolterodine. After 2 years of follow-up, persistence on oxybutynin (9.4%) was significantly lower than that on tolterodine (13.6%, $P < .0001$). The median times to discontinuation of oxybutynin and tolterodine were 68 and 128 days, respectively. Kessler and colleagues (2011) analyzed 69 trials enrolling 26,229 patients with OAB; the aim was to compare adverse events of antimuscarinics using a network meta-analytic approach that overcomes shortcomings of conventional analyses. They found similar overall adverse event profiles for darifenacin, fesoterodine, transdermal oxybutynin, propiverine, solifenacin, tolterodine, and trospium chloride, but not for oxybutynin orally administered when currently used starting dosages were compared. They concluded that most currently used antimuscarinics seem to be equivalent first-choice drugs to start the treatment of OAB, except for oral oxybutynin doses of 10 mg/day or more, which may have more unfavorable adverse event profiles.

Adverse Effects. Even if the use of antimuscarinics is associated with many adverse effects, they are generally considered to be "safe" drugs. However, among the more serious concerns related to their use is the risk of cardiac adverse effects, particularly QT prolongation and induction of polymorphic ventricular tachycardia (torsades de pointes), and increases in HR (Andersson and Olshansky, 2007; Andersson, 2011c; Rosa et al, 2013). QT prolongation and its consequences are not related to blockade of muscarinic receptors, but rather linked to inhibition of the hERG potassium channel in the heart (Roden, 2004). Thus, QT prolongation is not a class effect of antimuscarinics. However, the experiences with terodiline, an antimuscarinic drug that caused torsades de pointes in patients (Connolly et al, 1991; Stewart et al, 1992), have placed the whole drug class under scrutiny.

The parasympathetic actions on the heart oppose the excitatory actions of the sympathetic nervous system and slow the HR. An elevated resting HR has been linked to overall increased morbidity

and mortality, particularly in patients with cardiovascular diseases. The prevalence of cardiovascular comorbidities was found to be significantly higher in patients with than without OAB (Andersson et al, 2010b). Because mean changes in HR reported in population studies might not be applicable to an individual patient, and particularly in patients at risk of cardiac disease, even moderate increases in HR might be harmful. The potential of the different antimuscarinic agents to increase HR and/or prolong the QT time has not been extensively explored for all agents in clinical use. Differences among drugs cannot be excluded, but risk assessments based on available evidence are not possible.

Another concern is that antimuscarinic drugs commonly used to treat OAB can be associated with CNS side effects including cognitive dysfunction, memory impairment, dizziness, fatigue, and headache. With the exception of oxybutynin IR, CNS-related side effects are not commonly found when investigated. The potential to cause CNS-related adverse effects may differ among drugs, but in the absence of comparative trials, relative risk assessments are not possible.

Antimuscarinics with Specific Action

Here, data on the different antimuscarinics are presented. These drugs are assumed to block only muscarinic receptors (motivating the term *specific*). The amount of information for the individual drugs varies, and so does the degree of detail from the different studies presented. However, the information has been chosen to give a reasonable efficacy and adverse effect profile of each individual drug.

Atropine Sulfate. Atropine (*dl*-hyoscyamine) is rarely used for treatment of OAB or DO because of its systemic side effects, which preclude its use as an oral treatment. However, in patients with NDO, intravesical atropine may be effective for increasing bladder capacity without causing any systemic adverse effects, as shown in open pilot trials (Ekström et al, 1992; Glickman et al, 1995; Deaney et al, 1998; Enskat et al, 2001; Fader et al, 2007). It appears that intravesical atropine may be as effective as intravesical oxybutynin in patients with NDO (Fader et al, 2007).

The pharmacologically active antimuscarinic component of atropine is L-hyoscyamine. Although still used, few clinical studies are available to evaluate the antimuscarinic activity of L-hyoscyamine sulfate (Muskat et al, 1996). For assessment, see Table 79-3.

Darifenacin Hydrobromide. Darifenacin is a tertiary amine with moderate lipophilicity, well absorbed from the gastrointestinal tract after oral administration, and extensively metabolized in the liver by the cytochrome P450 isoforms CYP3A4 and CYP2D6, the latter saturating within the therapeutic range (Skerjanec, 2006). UK-148993, UK-73689, and UK-88862 are the three main circulating darifenacin metabolites, of which only UK-148993 is said to have significant antimuscarinic activity. However, available information suggests that various metabolites of darifenacin contribute little to its clinical effects (Michel and Hegde, 2006). The metabolism of darifenacin by CYP3A4 suggests that coadministration of a potent inhibitor of this enzyme (e.g., ketoconazole) may lead to an increase in the circulating concentration of darifenacin (Kerbusch et al, 2003).

Darifenacin is a relatively selective muscarinic M₃-receptor antagonist. In vitro, it is selective for human cloned muscarinic M₃ receptors relative to M₁, M₂, M₄, or M₅ receptors. Theoretically, drugs with selectivity for the M₃ receptor can be expected to have clinical efficacy in OAB and DO with reduction of the adverse events related to the blockade of other muscarinic receptor subtypes (Andersson, 2002b). However, the clinical efficacy and adverse effects of a drug are dependent not only on its profile of receptor affinity, but also on its pharmacokinetics, and on the importance of muscarinic receptors for a given organ function.

Darifenacin has been developed as a controlled-release formulation, which allows once-daily administration. Recommended doses are 7.5 and 15 mg/day. The clinical effectiveness of the drug has been documented in several randomized controlled trials (RCTs) (Haab et al, 2004; Cardozo and Dixon, 2005; Chapple et al, 2005b;

Foote et al, 2005; Steers et al, 2005; Haab et al, 2006; Hill et al, 2006; Zinner et al, 2006; Chapple et al, 2007a; Abrams et al, 2008; Chancellor et al, 2008b; Dwyer et al, 2008; for reviews, see Guay, 2005; Zinner, 2007; Chapple et al, 2008a; Novara et al, 2008). Haab and colleagues (2004) reported a multicenter, double-blind, placebo-controlled, parallel-group study that enrolled 561 patients (19 to 88 years; 85% female) with OAB symptoms for more than 6 months, and included some patients with prior exposure to antimuscarinic agents. After washout and a 2-week placebo run-in, patients were randomized (1:4:2:3) to once-daily oral darifenacin controlled-release tablets, 3.75 mg (n = 53), 7.5 mg (n = 229), or 15 mg (n = 115), or matching placebo (n = 164) for 12 weeks. Using an electronic diary during weeks 2, 6, and 12 (directly preceding clinic visits), patients recorded daily incontinence episodes, micturition frequency, bladder capacity (mean voided volume [MVV]), frequency of urgency, severity of urgency, incontinence episodes resulting in change of clothing or pads, and nocturnal awakenings caused by OAB. Tolerability data were evaluated from adverse event reports. Darifenacin 7.5 mg and 15 mg had a rapid onset of effect, with significant improvement compared with placebo being seen for most parameters at the first clinic visit (week 2). Darifenacin 7.5 mg and 15 mg were significantly superior to placebo for (median) improvements in micturition frequency (7.5 mg, -1.6; 15 mg, -1.7; placebo, -0.8), frequency of urgency per day (-2.0; -2.0; -0.9), and number of incontinence episodes leading to a change in clothing or pads (-4.0; -4.7; -2.0). There was no significant reduction in nocturnal awakenings caused by OAB. The most common adverse events were mild-to-moderate dry mouth and constipation, with a CNS and cardiac safety profile comparable to placebo. No patients withdrew from the study as a result of dry mouth, and discontinuation related to constipation was rare (0.6% for placebo vs. 0.9% for darifenacin).

In a dose titration study on 395 OAB patients, darifenacin, allowing individualized dosage (7.5 or 15 mg), was found to be effective and well-tolerated (Steers et al, 2005). A 2-year open-label extension study of these investigations (Haab et al, 2004; Steers et al, 2005), confirmed a favorable efficacy, tolerability, and safety profile (Haab et al, 2006).

A review of the pooled darifenacin data from the three phase III, multicenter, double-blind clinical trials in patients with OAB was reported by Chapple and colleagues (2005b). After a 4-week washout and run-in period, 1059 adults (85% female) with symptoms of OAB (urgency incontinence, urgency, and frequency) for at least 6 months were randomized to once-daily oral treatment with darifenacin 7.5 mg (n = 337) or 15 mg (n = 334) or matching placebo (n = 388) for 12 weeks. Efficacy was evaluated using electronic patient diaries that recorded incontinence episodes (including those resulting in a change of clothing or pads), frequency and severity of urgency, micturition frequency, and bladder capacity (volume voided). Safety was evaluated by analysis of treatment-related adverse events, withdrawal rates, and laboratory tests. Relative to baseline, 12 weeks of treatment with darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week (7.5 mg, -8.8 [-68.4%; placebo -54%, $P < .004$]; 15 mg, -10.6 [-76.8%; placebo 58%, $P < .001$]). Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation, although together these resulted in few discontinuations (darifenacin 7.5 mg, 0.6% of patients; darifenacin 15 mg, 2.1%; placebo, 0.3%). The incidence of CNS and cardiovascular adverse events were comparable to placebo. The results were confirmed in other RCTs, including also a pooled analysis of three phase III studies in older patients (≥ 65 years), showing that darifenacin (7.5 and 15 mg) had an excellent efficacy, tolerability, and safety profile (Foote et al, 2005; Zinner et al, 2005; Hill et al, 2006).

The time to effect with darifenacin was analyzed in a pooled analysis of efficacy and safety data from 1059 patients participating

in three double-blind 12-week studies (Khullar et al, 2011). Darifenacin significantly improved all OAB symptoms as early as 6 to 8 days.

One of the most noticeable clinical effects of antimuscarinics is their ability to reduce urgency and allow patients to postpone micturition. A study was conducted to assess the effect of darifenacin on the warning time associated with urinary urgency. Warning time was defined as the time from the first sensation of urgency to the time of voluntary micturition or incontinence. This was a multicenter, randomized, double-blind, placebo-controlled study consisting of 2 weeks' washout, 2 weeks' medication-free run-in, and a 2-week treatment phase (Cardozo and Dixon, 2005). Warning time was defined as the time from the first sensation of urgency to voluntary micturition or incontinence and was recorded via an electronic event recorder at baseline (visit 3) and study end (visit 4) during a 6-hour clinic-based monitoring period, with the subject instructed to delay micturition for as long as possible. During each monitoring period, up to three urgency-void cycles were recorded. Of the 72 subjects who entered the study, 67 had warning time data recorded at both baseline and study end and were included in the primary efficacy analysis (32 on darifenacin, 35 on placebo). Darifenacin treatment resulted in a significant ($P < .004$) increase in mean warning time, with a median increase of 4.3 minutes compared with placebo (darifenacin group from 4.4 to 1.8 minutes; placebo from 7.0 to -1.0 minutes). Overall, 47% of darifenacin-treated subjects compared with 20% receiving placebo achieved a 30% or greater increase in mean warning time. There were methodologic problems associated with this study; it used a dose of 30 mg (higher than the dose recommended for clinical use), the treatment period was short, it was conducted in a clinical-centered environment, the methodology carried with it a significant potential training effect, and the placebo group had higher baseline values than the treatment group. In another warning time study (Zinner et al, 2006) on 445 OAB patients, darifenacin treatment (15 mg) resulted in numeric increases in warning time; however, these were not significant compared with placebo.

Further studies have demonstrated that darifenacin treatment is associated with clinically relevant improvements in health-related quality of life (QoL) in patients with OAB (Abrams et al, 2008), and such improvements were sustained as shown in a 2-year extension study (Dwyer et al, 2008). It was shown that neither the positive effects on micturition variables nor those on health-related QoL produced by darifenacin (7.5 and 15 mg) were further enhanced by a behavioral modification program including timed voiding, dietary modifications, and Kegel exercises (Chancellor et al, 2008b).

Because darifenacin is a substrate for the P-glycoprotein drug efflux transporter (Miller et al, 2011; Chancellor et al, 2012), which is present in both the blood-brain and the blood-ocular barriers, several clinical studies have been devoted to investigate possible effects of darifenacin on cognition. Neither in healthy volunteers aged 19 to 44 years and healthy patients 60 years or older nor in volunteers 65 years or older could any effect of darifenacin (3.75 to 15 mg daily) be demonstrated, compared with placebo (Kay and Wesnes, 2005; Lipton et al, 2005; Kay et al, 2006; Kay and Ebinger 2008; Chancellor et al, 2012).

To study whether darifenacin had any effect on QT and QTc intervals, Serra and colleagues (2005) performed a 7-day, randomized, parallel-group study ($n = 188$) in healthy volunteers receiving once-daily darifenacin at steady-state therapeutic (15 mg) and supratherapeutic (75 mg) doses, alongside controls receiving placebo or moxifloxacin (positive control, 400 mg) once daily. No significant increase in QTcF interval could be demonstrated compared with placebo. Mean changes from baseline at pharmacokinetic T_{max} versus placebo were -0.4 and -2.2 msec in the darifenacin 15-mg and 75-mg groups, respectively, compared with +11.6 msec in the moxifloxacin group ($P < .01$). The conclusion was that darifenacin does not prolong the QT or QTc interval.

Darifenacin 15 mg/day given to healthy volunteers did not change HR significantly compared with placebo (Olshansky et al, 2008).

Assessment. Darifenacin has a well-documented beneficial effect in OAB and DO (see Table 79-3), and tolerability and safety seem acceptable.

Fesoterodine Fumarate. Fesoterodine functions as an orally active prodrug that is converted to the active metabolite 5-HMT by nonspecific esterases (Michel, 2008; Malhotra et al, 2009b). This compound, which is chemically identical to the 5-hydroxy metabolite of tolterodine, is a non-subtype selective muscarinic-receptor antagonist (Ney et al, 2008). All of the effects of fesoterodine in man are thought to be mediated via 5-HMT, because the parent compound remains undetectable after oral administration. 5-HMT is metabolized in the liver, but a significant part of 5-HMT is excreted renally without additional metabolism. Because the renal clearance of 5-HMT is about 250 mL/min, with more than 15% of the administered fesoterodine dose excreted as unchanged 5-HMT, this raises the possibility that 5-HMT also could work from the luminal side of the bladder (Michel, 2008). The bioavailability of fesoterodine, averaging 52%, was independent of food intake, and the drug may be taken with or without a meal (Malhotra et al, 2009c). Peak plasma concentration of 5-HMT is reached at 5 hours after oral administration, and the agent has a half-life of 7 to 9 hours (Malhotra et al, 2008). The suggested starting dose, 4 mg/day, can be used in patients with moderately impaired renal or hepatic function because of the combination of renal excretion and hepatic metabolism of 5-HMT (Malhotra et al, 2009a; de Mey et al, 2011).

The clinical efficacy and tolerability of fesoterodine have been documented in several RCTs (Chapple et al, 2007b; Nitti et al, 2007; Dmochowski et al, 2010c; Herschorn et al, 2010; Nitti et al, 2010; Kaplan et al, 2011; Dell'Utri et al, 2012). In a multicenter, double-blind, double-dummy RCT with tolterodine ER, 1132 patients were enrolled and received treatment (Chapple et al, 2007b). The trial showed that both the 4- and 8-mg doses of fesoterodine were effective in improving symptoms of OAB, with the 8-mg dose having a greater effect at the expense of a higher rate of dry mouth. There appeared to be little difference between fesoterodine 4 mg and tolterodine ER. Only 1 patient from the fesoterodine 8-mg group and 1 patient from the tolterodine ER group withdrew from the study because of dry mouth. The dose-response relationship was confirmed in another study that pooled data from two phase III RCTs (Khullar et al, 2008). Fesoterodine 8 mg performed better than the 4-mg dose in improving urgency and urge UI as recorded by 3-day bladder diary, offering the possibility of dose titration.

A head-to-head placebo-controlled trial has been completed comparing fesoterodine 8 mg with tolterodine ER 4 mg and placebo (Herschorn et al, 2010). The study randomized 1590 patients to assess the primary outcome of reduced urgency incontinence episodes at 12 weeks. Fesoterodine produced statistically significant improvements in urgency incontinence episodes, complete dry rates (64.0% vs. 57.2%, $P = .015$), and MVV per void (+32.9 mL vs. +23.5 mL, $P = .005$) and in patients' assessments of bladder-related problems as measured by OAB questionnaire (except sleep domain), Patient Perception of Bladder Condition (40% vs. 33% with >2-point improvement, $P < .001$), and Urgency Perception Scale (46% vs. 40% with improvement, $P = .014$) compared with tolterodine. The clinical significance of these statistically significant findings is questionable because there was no difference between agents with respect to number of micturitions, urgency episodes, and frequency-urgency sum per 24 hours. The improved efficacy of fesoterodine came at the cost of greater dry mouth (27.8% vs. 16.4%), headache (5.6% vs. 3.4%), constipation (5.4% vs. 4.1%), and withdrawal rates (6% vs. 4%). Nonetheless, this first head-to-head trial comparing two drugs in class supports the use of fesoterodine 8 mg for additional benefit over tolterodine ER 4 mg.

Wyndaele and colleagues (2009) reported the first flexible-dose open-label fesoterodine trial, which was conducted at 80 different centers worldwide and included 516 participants (men and women) older than 18 years who self-reported OAB symptoms for at least 3 months before screening and had been treated with either tolterodine or tolterodine ER within 2 years without symptom improvement. Approximately 50% opted for dose escalation to 8 mg at

week 4. Significant improvements from baseline to week 12 were observed in micturitions, urgency urinary incontinence (UUI) episodes, micturition-related urgency episodes, and severe micturition-related urgency episodes per 24 hours. Significant improvements from baseline were observed in QoL parameters. Dry mouth (23%) and constipation (5%) were the most common adverse events; no safety issues were identified.

The largest double-blind, double-dummy, flexible-dose fesoterodine RCT, which was conducted at 210 different centers with a total of 2417 patients enrolled, was performed by [Kaplan and colleagues \(2011\)](#). All patients were healthy, older than 18 years, and self-reported OAB symptoms for at least 3 months. The 960 patients who received fesoterodine 8 mg showed significantly greater mean improvements at week 12 in most efficacy parameters (diary variables)—UUI and urgency episodes, micturition frequency, and MVV—than those receiving either tolterodine ER or placebo. No statistically significant changes were shown in reduction of nocturnal micturitions compared with the tolterodine group, whereas when comparing the mean changes in nighttime micturition with the placebo group a significant difference was found. This phase III study confirmed the superiority of fesoterodine 8 mg over tolterodine ER 4 mg for improving UUI and urgency episodes and 24-hour micturitions but not for MVV and nocturia. In another RCT of flexible-dose fesoterodine, [Dmochowski and colleagues \(2010c\)](#) reported statistically significant improvements at week 12 in the mean number of micturition per 24 hours and in both UUI and urgency episodes. Between groups, difference in nocturnal micturition was not statistically significant.

[Nitti and colleagues \(2010\)](#) determined whether the presence of DO in patients with OAB and UUI was a predictor of the response to treatment with fesoterodine in a phase II randomized, multicenter, placebo-controlled trial. They concluded that regardless of the presence of DO, the response to fesoterodine treatment was dose proportional and associated with significant improvements in OAB symptoms, indicating that **the response to OAB pharmacotherapy in patients with UUI was independent of the urodynamic diagnosis of DO.**

[Kelleher and colleagues \(2008\)](#) evaluated the effect of fesoterodine on health-related QoL in patients with OAB syndrome. Pooled data from two randomized placebo-controlled phase III studies ([Chapple et al, 2007b](#); [Nitti et al, 2007](#)) were analyzed. Eligible patients were randomized to placebo or fesoterodine 4 or 8 mg for 12 weeks; one trial also included tolterodine ER 4 mg. By the end of treatment, all active-treatment groups had significantly improved health-related QoL compared with those on placebo. In a post hoc analysis of data pooled from these studies, significant improvements in all King's Health Questionnaire (KHQ) domains, International Consultation on Incontinence Questionnaire Short Form (ICIQ-IUSF) scores, and bladder-related problems were observed at months 12 and 24 compared with open-label baseline ([Kelleher et al, 2012](#)). The authors concluded that treatment satisfaction was high throughout the open-label treatment regardless of gender and age.

[Malhotra and colleagues \(2010\)](#) performed a thorough QT study to investigate the effects of fesoterodine on cardiac repolarization in a parallel-group study. Subjects were randomly assigned to receive double-blind fesoterodine 4 mg, fesoterodine 28 mg, or placebo or open-label moxifloxacin 400 mg (positive control) for 3 days. Electrocardiograms (ECGs) were obtained on days 1 (baseline) and 3. The primary analysis was of the time-averaged changes from baseline for Fridericia's corrected QT interval (QTcF) on day 3. Among 261 subjects randomized to fesoterodine 4 mg ($n = 64$), fesoterodine 28 mg ($n = 68$), placebo ($n = 65$), or moxifloxacin 400 mg ($n = 64$), 256 completed the trial. The results indicated that fesoterodine is not associated with QTc prolongation or other ECG abnormalities at either therapeutic or supratherapeutic doses.

Assessment. Fesoterodine has a well-documented beneficial effect in OAB (see [Table 79-3](#)), and the adverse event profile seems acceptable.

Imidafenacin. Imidafenacin (KRP-197/ONO-8025, 4-[2-methyl-1H-imidazol-1-yl]-2,2-diphenylbutanamide) is an antagonist for

the muscarinic ACh receptor with higher affinities for M_3 and M_1 receptors than for the M_2 receptor. Metabolites of imidafenacin (M-2, M-4 and M-9) had low affinities for muscarinic ACh receptor subtypes ([Kobayashi et al, 2007](#)). The drug blocks prejunctional as well as postjunctional muscarinic receptors and was shown to block both detrusor contractions and ACh release ([Murakami et al, 2003](#)). The receptor binding affinity of imidafenacin in vitro was found to be significantly lower in the bladder than submaxillary gland or colon ([Yamada et al, 2011](#)), and in rats orally administered imidafenacin distributes predominantly to the bladder and exerts more selective and longer-lasting effect there than on other tissues. Whether this can be translated to the human situation has to be established before claims of clinical bladder selectivity can be made.

Imidafenacin is well absorbed from the gastrointestinal tract, and its absolute bioavailability in humans is 57.8% ([Ohmori et al, 2007](#); [Ohno et al, 2008](#)). It is rapidly absorbed with maximum plasma concentration occurring 1 to 3 hours after oral administration ([Ohno et al, 2008](#)). Metabolites in the plasma are produced mainly by first-pass effects. The major enzymes responsible for the metabolism of the drug are CYP3A4 and UGT1A4. The oxidative metabolism is reduced by concomitant administration of CYP3A4 inhibitors. In contrast, imidafenacin and its metabolites have no inhibitory effect on the CYP-mediated metabolism of concomitant drugs ([Kanayama et al, 2007](#)).

[Kitagawa and colleagues \(2011\)](#) reported that the subjective efficacy of imidafenacin was observed from 3 days after the commencement of administration and that mean total Overactive Bladder Symptom Score decreased gradually during 2 weeks after administration.

A randomized, double-blind, placebo-controlled phase II dose-finding study in Japanese OAB patients was performed to evaluate the efficacy, safety and tolerability, and dose-response relationship of imidafenacin ([Homma et al, 2008](#)). Overall, 401 patients were enrolled and randomized for treatment with 0.1 mg of imidafenacin per day (99 patients), 0.2 mg of imidafenacin per day (100), 0.5 mg of imidafenacin per day (101), or a placebo (101). After 12 weeks of treatment, the number of incontinence episodes was reduced in a dose-dependent manner, and a significant difference between the imidafenacin treatment and the placebo groups was observed ($P < .0001$). Compared with the placebo, imidafenacin caused significant reductions in urgency incontinence, voiding frequency, and urinary urgency, and a significant increase in the urine volume voided per micturition. Imidafenacin was also well tolerated. The incidence of dry mouth in the imidafenacin groups increased in a dose-dependent manner. Even though the percentage of patients receiving 0.5 mg/day who discontinued treatment because of dry mouth was high (8.9%), the percentages in the 0.1 mg/day and 0.2 mg/day groups (1.0% and 0.0%, respectively) were comparable with that in the placebo group (0.0%).

A randomized, double-blind, placebo- and propiverine-controlled trial of 781 Japanese patients with OAB symptoms was conducted by Homma and coworkers ([Homma and Yamaguchi, 2009](#)). Patients were randomized to imidafenacin (324), propiverine (310), or a placebo (147). After 12 weeks of treatment, a significantly larger reduction in the mean number of incontinence episodes was observed in the imidafenacin group than in the placebo group ($P < .0001$). The noninferiority of imidafenacin compared with propiverine was confirmed for the reduction in UI episodes ($P = .0014$; noninferiority margin, 14.5%). Imidafenacin was well tolerated. The incidence of adverse events with imidafenacin was significantly lower than with propiverine ($P = .0101$). Dry mouth, the most common adverse event, was significantly more common in the propiverine group than in the imidafenacin group. There were no significant increases in either the imidafenacin or the placebo group in the mean QTc interval, whereas there was a significant increase in the mean QTc interval in the propiverine group ($P < .0001$). However, clinical arrhythmia and clinical arrhythmic events were not seen in any of the treatment groups.

The long-term safety, tolerability, and efficacy of imidafenacin were studied in Japanese OAB patients ([Homma and Yamaguchi, 2008](#)), of whom 478 received treatment and 376 completed a

52-week program. Imidafenacin was well tolerated, the most common adverse event being a dry mouth (40.2% of the patients). Long-term treatment did not produce an increase in the frequency of adverse events compared with short-term treatment. A significant efficacy of the drug was observed from week 4 through week 52. After 52 weeks, imidafenacin had produced mean changes from baseline in the number of incontinence episodes (−83.51%), urgency incontinence episodes (−84.21%), voiding frequency (−2.35 micturitions per day), urgency episodes (−70.53%), and volume voided per micturition (28.99 mL). There were also significant reductions from baseline in all domains of the KHQ. Imidafenacin had no significant effects on the corrected QT interval, vital signs, results from laboratory tests, or postvoid residual (PVR) volume).

A 52-week prospective, open randomized comparative study to evaluate the efficacy and tolerability of imidafenacin (0.2 mg/day) and solifenacin (5 mg/day) was conducted in a total of 41 Japanese patients with untreated OAB (Zaitsu et al, 2011). They were randomly assigned to imidafenacin and solifenacin groups. There were no differences in OAB and KHQ scores between the two groups, but the severity and incidence of adverse events caused by the drugs showed increased differences between the groups with time. The severity of dry mouth and the incidence of constipation were significantly lower in the imidafenacin group ($P = .0092$ and $P = .0013$, respectively). An important limitation of this study is the low number of patients. Only 25 patients (17 male, 8 female) were available for long-term analysis.

Assessment. Imidafenacin seems to be effective and to have an acceptable tolerability. However, the documentation is relatively scarce and the drug is not yet available in the Western countries.

Propantheline Bromide. Propantheline is a quaternary ammonium compound, nonselective for muscarinic receptor subtypes, which has a low (5% to 10%) and individually varying biologic availability. It is metabolized (metabolites inactive) and has a short half-life (less than 2 hours) (Beermann et al, 1972). It is usually given in a dose of 15 to 30 mg four times daily, but to obtain an optimal effect, individual titration of the dose is necessary, and often higher doses are required. Using this approach in 26 patients with DO contractions, Blaivas and colleagues (1980) in an open study obtained a complete clinical response in all patients but 1, who did not tolerate more than propantheline 15 mg four times daily. The range of doses varied from 7.5 to 60 mg four times daily. In contrast, Thüroff and colleagues (1991), comparing the effects of oxybutynin 5 mg three times daily, propantheline 15 mg three times daily, and placebo in a randomized, double-blind, multicenter trial on the treatment of frequency, urgency, and incontinence related to DO (154 patients), found no differences between the placebo and propantheline groups. In another randomized comparative trial with crossover design (23 women with idiopathic detrusor overactivity [IDO]) and with dose titration, Holmes and colleagues (1989) found no differences in efficacy between oxybutynin and propantheline. Six controlled randomized trials reviewed by Thüroff and colleagues (1998) confirmed a positive but varying response to the drug.

Assessment. Although the effect of propantheline on OAB and DO has not been well documented in controlled trials satisfying standards of today, it can be considered effective, and may, in individually titrated doses, be clinically useful (see Table 79-3). No new studies on the use of this drug for treatment of OAB and DO seem to have been performed during the last decade.

Solifenacin Succinate. Solifenacin succinate (YM905) is a tertiary amine that is well absorbed from the gastrointestinal tract (absolute bioavailability 90%). The mean terminal half-life is 45 to 68 hours (Kuipers et al, 2002; Smulders et al, 2002, 2004). It undergoes significant hepatic metabolism involving the cytochrome P450 enzyme system (CYP3A4). In patients who received a single oral dose of 10 mg solifenacin on day 7 of a 20-day regimen of ketoconazole administration (200 mg), C_{max} and AUC_{0-inf} were increased by only approximately 40% and 56%, respectively (Swart et al, 2006). Solifenacin has a modest selectivity for M₃ over M₂ (and M₁) receptors (Abrams and Andersson, 2007).

Supporting an effect of solifenacin on sensory function, 15 women with DO receiving 10 mg of the drug per day showed an increase in the area under the bladder-volume sensation curve (Lowenstein et al, 2012). Solifenacin also increased maximum bladder capacity, a finding in agreement with other studies (Tanaka et al, 2010; Hsiao et al, 2011).

Two large-scale phase II trials with parallel designs, including men and women, were performed (Smith et al, 2002; Chapple et al, 2004a). The first dose-ranging study evaluated solifenacin 2.5 mg, 5 mg, 10 mg, and 20 mg and tolterodine (2 mg twice daily) in a multinational placebo-controlled study of 225 patients with uroynamically confirmed DO (Chapple et al, 2004a). Patients received treatment for 4 weeks followed by 2 weeks of follow-up. Inclusion criteria for this and subsequent phase III studies of patients with OAB included at least eight micturitions per 24 hours and either one episode of incontinence or one episode of urgency daily as recorded in 3-day micturition diaries. Micturition frequency, the primary efficacy variable, was statistically significantly reduced in patients taking solifenacin 5 mg (−2.21), 10 mg (−2.47), and 20 mg (−2.75), but not in patients receiving placebo (−1.03) or tolterodine (−1.79). This effect was rapid, with most of the effect observed at the earliest assessment visit, 2 weeks after treatment initiation. In addition, there were numerically greater reductions in episodes of urgency and incontinence when compared with placebo. Study discontinuations caused by adverse events were similar across treatment groups, albeit highest in the 20-mg solifenacin group. Because the 5-mg and 10-mg doses caused lower rates of dry mouth than tolterodine and had superior efficacy outcomes relative to placebo, these dosage strengths were selected for further evaluation in large-scale phase III studies.

The second dose-ranging study of solifenacin 2.5 mg to 20 mg was carried out in the United States (Smith et al, 2002). This trial included 261 evaluable men and women receiving solifenacin or placebo for 4 weeks followed by a 2-week follow-up period. Micturition frequency was statistically significantly reduced relative to placebo in patients receiving 10 mg and 20 mg of solifenacin. The number of micturitions per 24 hours showed reductions by day 7 and continued to decrease through day 28; day 7 was the earliest time point tested in solifenacin trials, and these findings demonstrate efficacy as early as 1 week. The 5-mg, 10-mg, and 20-mg dosage groups experienced statistically significant increases in volume voided; the 10-mg solifenacin dose was associated with statistically significant reductions in episodes of incontinence.

In one of the early RCTs, 1077 patients were randomized to 5-mg solifenacin, 10-mg solifenacin, tolterodine (2 mg twice daily), or placebo (Chapple et al, 2004b). It should be noted that this study was powered only to compare active treatments with placebo. Compared with placebo (−8%), mean micturitions per 24 hours were significantly reduced with solifenacin 10 mg (−20%), solifenacin 5 mg (−17%), and tolterodine (−15%). Solifenacin was well tolerated, with few patients discontinuing treatment. Incidences of dry mouth were 4.9% with placebo, 14.0% with solifenacin 5 mg, 21.3% with solifenacin 10 mg, and 18.6% with tolterodine 2 mg twice daily.

Cardozo and colleagues (2004b) randomized 911 patients to 12-week once-daily treatment with solifenacin 5 mg, solifenacin 10 mg, or placebo. The primary efficacy variable was change from baseline to study end point in mean number of micturitions per 24 hours. Secondary efficacy variables included changes from baseline in mean number of urgency, nocturia, and incontinence episodes per 24 hours, and MVV per micturition. Compared with changes obtained with placebo (−1.6), the number of micturitions per 24 hours was statistically significantly decreased with solifenacin 5 mg (−2.37) and 10 mg (−2.81). A statistically significant decrease was observed in the number of all incontinence episodes with both solifenacin doses (5 mg, −1.63, 61%; 10 mg, −1.57, 52%), but not with placebo (−1.25, 28%). Of patients reporting incontinence at baseline, 50% achieved continence after treatment with solifenacin (based on a 3-day micturition diary, placebo responses not given). Episodes of nocturia were statistically significantly decreased in patients treated with solifenacin 10 mg versus placebo. Episodes of

urgency and MVV per micturition were statistically significantly reduced with solifenacin 5 mg and 10 mg. Treatment with solifenacin was well tolerated. Dry mouth, mostly mild in severity, was reported in 7.7% of patients receiving solifenacin 5 mg and 23% receiving solifenacin 10 mg (vs. 2.3% with placebo). A 40-week follow-up of these studies (Cardozo et al, 2004b; Chapple et al, 2004b) demonstrated that the favorable profile, both in terms of efficacy and tolerability, was maintained over the study period (Haab et al, 2005).

The STAR trial (Chapple et al, 2005c, 2007c) was a prospective, double-blind, double-dummy, two-arm, parallel-group, 12-week study conducted to compare the efficacy and safety of solifenacin 5 or 10 mg and tolterodine extended release (TOLT-ER) 4 mg once daily in OAB patients. The primary effect variable was micturition frequency. After 4 weeks of treatment patients had the option to request a dose increase, but were dummied throughout because approved product labeling allowed an increase only for those on solifenacin. The results showed that solifenacin, with a flexible dosing regimen, was noninferior to tolterodine with regard to the primary effect variable, micturition frequency. However, solifenacin showed significant greater efficacy to tolterodine in decreasing urgency episodes (−2.85 vs. −2.42), incontinence (−1.60 vs. −.83), urgency incontinence (−1.42 vs. −0.83), and pad use (−1.72 vs. −1.19). More solifenacin-treated patients became continent by study end point (59% vs. 49%) and reported improvements in perception of bladder condition (−1.51 vs. −1.33) assessments. However, this was accompanied by an adverse event incidence that was greater with solifenacin than with tolterodine. Dry mouth and constipation (mild, moderate, or severe) were the most common (solifenacin, 30 [6.4%]; tolterodine, 23 [2.5%]). The majority of side effects were mild to moderate in nature, and discontinuations were comparable and low (5.9% and 7.3%) in both groups.

Luo and colleagues (2012) performed a systematic review and meta-analysis of solifenacin RCTs and provided a comprehensive assessment regarding the efficacy and safety of the drug. Their results, which largely confirmed what could be deduced from previously published information, indicated that solifenacin significantly decreased the number of urgency episodes per 24 hours, micturitions per 24 hours, incontinence episodes per 24 hours, nighttime micturitions per 24 hours, and UUI episodes per 24 hours and improved volume voided per micturition compared with the placebo or tolterodine treatment.

A number of studies and reviews have further documented the effects of solifenacin (Cardozo et al, 2006; Chapple et al, 2006, 2007; Maniscalco et al, 2006; see also Chapple et al, 2008b; Novara et al, 2008; Toglia et al, 2009; Vardy et al, 2009; Serels et al, 2010; Luo et al, 2012), including in men with OAB without BOO (Kaplan et al, 2010). In a pooled analysis of four RCTs, Abrams and Swift (2005) demonstrated positive effects on urgency, frequency, and nocturia symptoms in OAB dry patients. In an analysis of four phase III clinical trials, Brubaker and FitzGerald (2007) confirmed a significant effect of solifenacin 5 and 10 mg on nocturia in patients with OAB (reductions of nocturia episodes with 5 mg, −0.6, $P < .025$; with 10 mg, −0.6, $P < .001$; vs. placebo, −0.4) but without nocturnal polyuria (NP). A positive impact on nocturia and sleep quality in patients with OAB treated with solifenacin has also been reported in other studies (Takao et al, 2011; Yokoyama et al, 2011). Kelleher and colleagues (2006) and Staskin and Te (2006) presented data showing efficacy in patients with mixed incontinence.

A pooled analysis of four studies confirmed the efficacy and tolerability of solifenacin 5 and 10 mg in elderly (65 years or older) patients and also showed a high level of persistence in a 40-week extension trial (Wagg et al, 2006). Post hoc analysis of two 12-week, open-label, flexible-dosage studies on 2645 patients older than 65 years with OAB revealed that solifenacin was associated with improvements in measures assessing patients' perception of their bladder problems, symptom bothersomeness, and aspects of health-related QoL (Capo' et al, 2011). Solifenacin was equally well tolerated in younger (<65 years) and older (>65 years) patients (Herschorn et al, 2011b). An exploratory pilot study with single doses of solifenacin 10 mg administered to 12 elderly volunteers

suggested no clear propensity to impair cognitive functions (Wesnes et al, 2009).

Improvement of QoL by solifenacin treatment has been documented in several studies (Kelleher et al, 2005; Garely et al, 2006). In 30 patients with multiple sclerosis, van Rey and Heesakkers (2011) improved OAB symptoms as well as neurogenic disease-specific QoL measures.

Information on solifenacin treatment in children is scarce. In a prospective open-label study in 72 children (27 with neurogenic bladders), Bolduc and colleagues (2010) improved urodynamic capacity and improved continence. Chart review of 138 children with therapy-resistant OAB treated with solifenacin increased MVV and improved continence (Hoebeke et al, 2009).

In female volunteers, aged 19 to 79 years, the effect of 10-mg and 30-mg solifenacin on the QT interval was evaluated at the time of peak solifenacin plasma concentration in a multidose, randomized, double-blind, placebo- and positive-controlled (moxifloxacin 400 mg) trial. The QT interval–prolonging effect appeared greater for the 30-mg (8 msec, 4, 13 [90% confidence interval (CI)]) compared with the 10-mg (2 msec, −3, 6) dose of solifenacin. Although the effect of the highest solifenacin dose (three times the maximum therapeutic dose) studied did not appear as large as that of the positive control moxifloxacin at its therapeutic dose, the CIs overlapped. This study was not designed to draw direct statistical conclusions between the drugs or the dose levels (Astellas prescribing information for VESicare, July 2010).

Michel and colleagues (2008) studied cardiovascular safety and overall tolerability of solifenacin in routine clinical use in a 12-week, open-label, postmarketing surveillance study. They concluded that “in real-life conditions, i.e., with inclusion of large numbers of patients with cardiovascular co-morbidities and taking comedications, therapeutically effective doses of solifenacin did not increase heart rate or blood pressure.”

Assessment. Solifenacin has a well-documented beneficial effect in OAB and DO (see Table 79-3), and the adverse event profile seems acceptable.

Tolterodine Tartrate. Tolterodine is a tertiary amine, rapidly absorbed and extensively metabolized by the cytochrome P450 system (CYP2D6). The major active 5-hydroxymethyl metabolite (5-HMT) has a similar pharmacologic profile as the mother compound (Nilvebrant et al, 1997b) and significantly contributes to the therapeutic effect of tolterodine (Brynne et al, 1997, 1998). Both tolterodine and 5-HMT have a plasma half-life of 2 to 3 hours, but the effects on the bladder seem to be longer lasting than could be expected from the pharmacokinetic data. Urinary excretion of tolterodine accounted for less than 1% to 2.4% of the dose; 5% to 14% of 5-HMT is eliminated in the urine (Brynne et al, 1997). Whether or not the total antimuscarinic activity of unchanged tolterodine and 5-HMT excreted in urine is sufficient to exert any effect on the mucosal signaling mechanisms has not been established. However, the preliminary studies by Kim and colleagues (2006) and Chuang and colleagues (2008) do not support such an effect.

The relatively low lipophilicity of tolterodine and even lesser one of 5-HMT imply limited propensity to penetrate into the CNS, which may explain a low incidence of cognitive side effects (Hills et al, 1998; Clemett and Jarvis, 2001; Salvatore et al, 2008). However, tolterodine may disturb sleep in subjects unable to form the even less lipophilic 5-HMT because of a low activity of CYP2D6 (Diefenbach et al, 2008).

Tolterodine has no selectivity for muscarinic receptor subtypes but is claimed to have functional selectivity for the bladder over the salivary glands (Stahl et al, 1995; Nilvebrant et al, 1997a). In healthy volunteers, oral tolterodine at a high dose (6.4 mg) had a powerful inhibitory effect on micturition and also reduced stimulated salivation 1 hour after administration of the drug (Stahl et al, 1995). However, 5 hours after administration, the effects on the urinary bladder were maintained, whereas no significant effects on salivation could be demonstrated.

Animal experiments have suggested that antimuscarinics may affect signaling from the bladder (Andersson et al, 2011b). Confirming data in humans were found by Vijaya and colleagues (2012). In

a randomized, placebo-controlled study, they evaluated the effect of tolterodine on urethral and bladder afferent nerves in women with DO compared with placebo, by studying the changes in the current perception threshold (CPT). They found a significantly increased CPT value at 5 (described as urgency) and 250 Hz on both urethral and bladder stimulation after 1 week of treatment. When compared with placebo, women taking tolterodine had significantly increased bladder CPT values at 5 Hz ($P < .05$).

Tolterodine is available in IR (TOLT-IR; 1 or 2 mg; twice-daily administration) and ER (TOLT-ER) forms (2 or 4 mg; once-daily administration). The ER form seems to have advantages over the IR form in terms of both efficacy and tolerability (Van Kerrebroeck et al, 2001).

Several randomized, double-blind, placebo-controlled studies on patients with OAB and DO (both IDO and NDO) have documented a significant reduction in micturition frequency and number of incontinence episodes (Hills et al, 1998; Clemett and Jarvis, 2001; Salvatore et al, 2008). Comparative RCTs such as the OBJECT (Overactive Bladder: Judging Effective Control and Treatment) and OPERA (Overactive Bladder: Performance of Extended Release Agents) studies have further supported its effectiveness.

The OBJECT trial compared oxybutynin ER (OXY-ER) 10 mg once daily with TOLT-IR 2 mg twice daily (Appell et al, 2001) in a 12-week randomized, double-blind, parallel-group study including 378 patients with OAB. Participants had 7 to 50 episodes of urgency incontinence per week and 10 or more voids in 24 hours. The outcome measures were the number of episodes of urgency incontinence, total incontinence, and micturition frequency at 12 weeks adjusted for baseline. At the end of the study, OXY-ER was found to be significantly more effective than TOLT-IR in each of the main outcome measures adjusted for baseline (see also the later discussion of *oxybutynin chloride*). Dry mouth, the most common adverse event, was reported by 33% and 28% of participants taking OXY-ER and TOLT-IR, respectively. Rates of CNS and other adverse events were low and similar in both groups. The authors concluded that OXY-ER was more effective than TOLT-IR and that the rates of dry mouth and other adverse events were similar in both treatment groups.

In the OPERA study (Diokno et al, 2003), OXY-ER at 10 mg/day or TOLT-ER at 4 mg/day were given for 12 weeks to women with 21 to 60 urgency incontinence episodes per week and an average of 10 or more voids per 24 hours. Episodes of incontinence (primary end point), total incontinence (urgency and nonurgency), and micturition were recorded in seven 24-hour urinary diaries at baseline and at weeks 2, 4, 8, and 12 and compared. Adverse events were also evaluated. Improvements in weekly urgency incontinence episodes were similar for the 790 women who received OXY-ER (391) or TOLT-ER (399). OXY-ER was significantly more effective than TOLT-ER in reducing micturition frequency, and 23.0% of women taking OXY-ER reported no episodes of UI compared with 16.8% of women taking TOLT-ER. Dry mouth, usually mild, was more common with OXY-ER. In general, adverse events were mild and occurred at low rates, with both groups having similar discontinuation of treatment because of adverse events. The conclusions were that reductions in weekly urgency incontinence and total incontinence episodes were similar with the two drugs. Dry mouth was more common with OXY-ER, but tolerability was otherwise comparable, including adverse events involving the CNS.

In the Antimuscarinic Clinical Effectiveness Trial (ACET) (Sussman and Garely, 2002), which consisted of two trials, patients with OAB were randomized to 8 weeks of open-label treatment with either 2 mg or 4 mg of once-daily TOLT-ER (study one) and to 5 mg or 10 mg of OXY-ER (study two). A total of 1289 patients were included. Fewer patients prematurely withdrew from the trial in the TOLT-ER 4-mg group (12%) than either the OXY-ER 5-mg (19%) or OXY-ER 10-mg groups (21%). More patients in the OXY-ER 10-mg group than in the TOLT-ER 4-mg group withdrew because of poor tolerability (13% vs. 6%). After 8 weeks, 70% of patients in the TOLT-ER 4-mg group perceived an improved bladder condition, compared with 60% in the TOLT-ER 2-mg group, 59% in the OXY-ER 5-mg group, and 60% in the OXY-ER 10-mg group. Dry

mouth was dose-dependent with both agents, although differences between doses reached statistical significance only in the oxybutynin trial (OXY-ER 5 mg vs. OXY-ER 10 mg; $P = .05$). Patients treated with TOLT-ER 4 mg reported a significantly lower severity of dry mouth compared with OXY-ER 10 mg. The conclusion that the findings suggest improved clinical efficacy of TOLT-ER (4 mg) than of OXY-ER (10 mg) is weakened by the the open-label design of the study.

Zinner and colleagues (2002) evaluated the efficacy, safety, and tolerability of TOLT-ER in older (≥ 65) and younger (< 65) OAB patients, in a 12-week RCT including 1015 patients with urgency incontinence and urinary frequency. Patients were randomized to treatment with TOLT-ER 4 mg once daily (507) or placebo (508) for 12 weeks. Efficacy, measured with micturition charts (incontinence episodes, micturitions, volume voided per micturition) and subjective patient assessments; safety; and tolerability end points were evaluated relative to placebo. Compared with placebo, significant improvements in micturition chart variables with TOLT-ER showed no age-related differences. Dry mouth (of any severity) was the most common adverse event in both the TOLT-ER and placebo treatment arms, irrespective of age (< 65 : ER 22.7%, placebo 8.1%; ≥ 65 : ER 24.3%, placebo 7.2%). A few patients ($< 2\%$) experienced severe dry mouth. No CNS (cognitive functions were not specifically studied), visual, cardiac (per ECG), or laboratory safety concerns were noted in this study. Withdrawal rates caused by adverse events on TOLT-ER 4 mg qd were comparable in the two age cohorts (< 65 : 5.5%; ≥ 65 : 5.1%).

The central symptom in the OAB syndrome is urgency. Freeman and colleagues (2003) presented a secondary analysis of a double-blind, placebo-controlled study evaluating the effect of once-daily TOLT-ER on urinary urgency in patients with OAB. Patients with urinary frequency (eight or more micturitions per 24 hours) and urgency incontinence (five or more episodes per week) were randomized to oral treatment with TOLT-ER 4 mg once daily ($n = 398$) or placebo ($n = 374$) for 12 weeks. Efficacy was assessed by use of patient perception evaluations. Of patients treated with TOLT-ER, 44% reported improved urgency symptoms (compared with 32% for placebo) and 62% reported improved bladder symptoms (placebo, 48%). The proportion of patients unable to hold urine on experiencing urgency was decreased by 58% with TOLT-ER, compared with 32% with placebo ($P < .001$).

In the Improvement in Patients: Assessing Symptomatic Control with Tolterodine ER (IMPACT) study (Elinoff et al, 2006), the efficacy of TOLT-ER for patients' most bothersome OAB symptom was investigated in an open-label primary care setting. Patients with OAB symptoms for 3 months or longer received TOLT-ER (4 mg once daily) for 12 weeks. By week 12, there were significant reductions in patients' most bothersome symptom: incontinence, urgency episodes, or nocturnal and daytime frequency. The most common adverse events were dry mouth (10%) and constipation (4%), and it was concluded that in primary care practice, bothersome OAB symptoms can be effectively and safely treated with TOLT-ER, even in patients with comorbid conditions.

Various aspects of the efficacy and tolerability of tolterodine have been further documented in a number of RCTs (Dmochowski et al, 2007a, 2007b; Bharucha et al, 2008; Choo et al, 2008; Coyne et al, 2008; Rogers et al, 2008; Rovner et al, 2008b; see also Chapple et al, 2008b; Novara et al, 2008). It is important to note that the QTc effects of tolterodine were determined in a crossover-designed QT study of recommended (2 mg twice daily) and supratherapeutic (4 mg twice daily) doses of tolterodine, moxifloxacin (400 mg once daily), and placebo. No subject receiving tolterodine exceeded the clinically relevant thresholds of 500-msec absolute QTc or 60-msec change from baseline, and it was concluded that tolterodine does not have a clinically significant effect on QT interval (Malhotra et al, 2007).

Olshansky and colleagues (2008) compared the effects on HR of TOLT-ER 4 mg/day with those of darifenacin 15 mg/day in healthy volunteers. They found that tolterodine, but not darifenacin, significantly increased mean HR per 24 hours. The proportion of subjects with an increase of more than 5 beats/min was

significantly greater in those receiving TOLT-ER (25%) than with darifenacin (8.9%).

Hsiao and colleagues (2011) compared the urodynamic effects, therapeutic efficacy, and safety of solifenacin (5 mg) versus tolterodine ER (4 mg) treatment in women with the OAB syndrome. Both solifenacin and tolterodine had similar urodynamic effects, therapeutic efficacy, and adverse events; however, tolterodine had a greater effect in increasing HR than solifenacin.

In a prospective, open study, Song and colleagues (2006) compared the effects of bladder training (BT) and/or tolterodine as first-line treatment in female patients with OAB. One hundred and thirty-nine female patients with OAB were randomized to treatment with BT, tolterodine (2 mg twice daily), or both for 12 weeks. All treatments were effective; however, combination therapy was the most effective. Mattiasson and colleagues (2003) compared the efficacy of tolterodine 2 mg twice daily plus simplified BT with tolterodine alone in patients with OAB in a multicenter single-blind study. At the end of the study the median percentage reduction in voiding frequency was greater with tolterodine plus BT than with tolterodine alone (33% vs. 25%; $P < .001$), whereas the median percentage increase in volume voided per void was 31% with tolterodine plus BT and 20% with tolterodine alone ($P < .001$). There was a median of 81% fewer incontinence episodes than at baseline with tolterodine alone, which was not significantly different from that with tolterodine plus BT (−87%). It was concluded that the effectiveness of tolterodine 2 mg twice daily can be augmented by a simplified BT regimen. However, Millard and the Asia Pacific Tolterodine Study Group (2004) investigated whether the combination of tolterodine plus a simple pelvic floor muscle exercise program would provide improved treatment benefits compared with tolterodine alone in 480 patients with OAB. Tolterodine therapy for 24 weeks resulted in significant improvement in urgency, frequency, and incontinence; however, no additional benefit was demonstrated for a simple pelvic floor muscle exercise program. In a 16-week, multicenter, open-label study, tolterodine ER plus behavioral intervention resulted in high treatment satisfaction and improved bladder diary variables in patients who had previously been treated and were dissatisfied with tolterodine or other antimuscarinics (Klutke et al, 2009).

Abrams and colleagues (2006c) studied the safety and tolerability of tolterodine for the treatment of OAB symptoms in men with BOO. They found that tolterodine did not adversely affect urinary function in these men. Urinary flow rate was unaltered, and there was no evidence of clinically meaningful changes in voiding pressure and PVR or urinary retention. It was suggested that antimuscarinics can be safely administered in men with BOO. Lee and colleagues (2008a) reviewed the safety and efficacy of antimuscarinic agents in treating men with BOO and OAB and emphasized their safety and efficacy. They also concluded that combination therapy with antimuscarinics and α_1 -adrenoceptor (α_1 -AR) antagonists improves the symptoms effectively without increasing the incidence of acute urinary retention (AUR).

The beneficial effect of TOLT-ER in men with BPE and LUTS, including OAB, has been well documented. Both as monotherapy, but particularly in combination with α_1 -AR antagonists, TOLT-ER was found effective (Kaplan et al, 2006, 2008a, 2008b; Höfner et al, 2007; Roehrborn et al, 2008a; Rovner et al, 2008a). This effect was obtained irrespective of prostate size and was not associated with increased incidence of AUR (Roehrborn et al, 2008a). A large, 26-week, multicenter, randomized, double-blind, placebo-controlled, three-period crossover study enrolled women aged 18 years or older who were diagnosed with OAB and reported eight or more micturitions per 24 hours and four or more urgency episodes per week on 5-day bladder diary at baseline (Marenca et al, 2011). Patients were randomized to 1 of 10 treatment sequences and received three of five treatments, each for 4 weeks with 4-week washout periods: standard-dose pregabalin/tolterodine ER (150 mg bid/4 mg qd; $n = 102$); pregabalin alone (150 mg bid; $n = 105$); tolterodine ER alone (4 mg qd; $n = 104$); low-dose pregabalin/tolterodine ER (75 mg bid/2 mg qd; $n = 105$); and placebo ($n = 103$). Patients completed 5-day diaries at the end of treatment and

washout periods. The primary end point was change from baseline to week 4 in MVV per micturition. Baseline-adjusted changes in MVV were significantly greater after treatment with standard-dose pregabalin/tolterodine ER (39.5 mL) versus tolterodine ER alone (15.5 mL; $P < .0001$) and with pregabalin alone (27.4 mL) versus tolterodine ER alone ($P = .005$) and placebo (11.9 mL; $P = .0006$). Treatments were generally well tolerated; discontinuation rates because of adverse events were 4%, 2%, 5%, 0%, and 1% with standard- and low-dose pregabalin/tolterodine ER, pregabalin, tolterodine ER, and placebo, respectively. See section on combination therapies for further information.

Assessment. Both the IR and ER forms of tolterodine have a well-documented effect in OAB and DO (see Table 79-3) and are well tolerated.

Trospium Chloride. Trospium is a quaternary ammonium compound with a biologic availability of less than 10% (Fusgen and Hauri, 2000; Doroshenko et al, 2005). The drug has a plasma half-life of approximately 20 hours, and is mainly (60% of the dose absorbed) eliminated unchanged in the urine. The concentration obtained in urine seems to be enough to affect the mucosal signaling system in a rat model (Kim et al, 2006). Whether or not it contributes to the clinical efficacy of the drug remains to be established.

Trospium is not metabolized by the cytochrome P450 enzyme system (Beckmann-Knopp et al, 1999; Doroshenko et al, 2005). It is expected to cross the blood-brain to a limited extent because it is a substrate for the drug-efflux transporter P-glycoprotein, which restricts its entry into the brain (Davis et al, 2014). This was demonstrated by Staskin and colleagues (2010), who showed that trospium chloride levels in cerebrospinal fluid (CSF) samples were undetectable on day 10 at steady-state peak plasma concentration concurrent with measureable peak plasma values. Clinically, trospium seems to have no negative cognitive effects (Fusgen and Hauri, 2000; Todorova et al, 2001; Wiedemann et al, 2002; Staskin et al, 2010; Chancellor et al, 2012).

Trospium has no selectivity for muscarinic receptor subtypes. In isolated detrusor muscle, it was more potent than oxybutynin and tolterodine to antagonize carbachol-induced contractions (Uckert et al, 2000).

Several RCTs have documented positive effects of trospium both in NDO (Stöhrer et al, 1991; Madersbacher et al, 1995; Menarini et al, 2006) and non-neurogenic DO (Alloussi et al, 1998; Cardozo et al, 2000; Jünemann and Al-Shukri, 2000; Halaska et al, 2003; Zinner et al, 2004; Rudy et al, 2006; Staskin et al, 2007; Dmochowski et al, 2008). In a placebo-controlled, double-blind study on patients with NDO (Stöhrer et al, 1991), the drug was given twice daily at a dose of 20 mg over a 3-week period. It increased maximum cystometric capacity, decreased maximal detrusor pressure, and increased compliance in the treatment group, whereas no effects were noted in the placebo group. Side effects were few and comparable in both groups. In another RCT including patients with spinal cord injuries and NDO, trospium and oxybutynin were equipotent; however, trospium seemed to have fewer side effects (Madersbacher et al, 1995).

The effect of trospium in urgency incontinence has been documented in several RCTs. Alloussi and colleagues (1998) compared the effects of the drug with those of placebo in 309 patients in a urodynamic study of 3 weeks' duration. Trospium 20 mg was given twice daily. Significant increases were noted in volume at first involuntary contraction and in maximum bladder capacity. Cardozo and colleagues (2000) investigated 208 patients with DO who were treated with trospium 20 mg twice daily for 2 weeks. Also in this study, significant increases were found in mean volume at first unstable contraction (from 233 to 299 mL; placebo, 254 to 255 mL) and in maximum bladder capacity (from 329 to 356 mL; placebo, 345 to 335 mL) in the trospium-treated group. Trospium was well tolerated with similar frequency of adverse effects as in the placebo group. Jünemann and Al-Shukri (2000) compared trospium 20 mg twice daily with tolterodine 2 mg twice daily in a placebo-controlled double-blind study on 232 patients with urodynamically proven DO, urgency incontinence without demonstrable DO, or mixed incontinence. Trospium reduced the frequency of micturition,

which was the primary end point, more than tolterodine and placebo, and also reduced the number of incontinence episodes more than the comparators. Dry mouth was comparable in the trospium and tolterodine groups (7% and 9%, respectively).

Halaska and colleagues (2003) studied the tolerability and efficacy of trospium chloride in doses of 20 mg twice daily for long-term therapy in patients with urgency syndrome. The trial included a total of 358 patients with urgency syndrome or urgency incontinence. After randomization in the ratio of 3:1, participants were treated continuously for 52 weeks with either trospium chloride (20 mg twice daily) or oxybutynin (5 mg twice daily). Urodynamic measurements were performed at the beginning and at 26 and 52 weeks to determine the maximal cystometric bladder capacity. Analysis of the micturition diary clearly indicated a reduction in the micturition frequency, incontinence frequency, and the number of urgency episodes in both treatment groups. Mean maximum cystometric bladder capacity increased during treatment with trospium chloride by 92 mL after 26 weeks and 115 mL after 52 weeks ($P = .001$). Further comparison with oxybutynin did not reveal any statistically significant differences in urodynamic variables between the drugs. Adverse events occurred in 65% of the patients treated with trospium and 77% of those treated with oxybutynin. The main symptom encountered in both treatment groups was dryness of the mouth. An overall assessment for each of the drugs revealed a comparable efficacy level and a better benefit-risk ratio for trospium than for oxybutynin resulting from better tolerability.

Zinner and colleagues (2004) treated 523 patients with symptoms associated with OAB and urgency incontinence with 20 mg trospium twice daily or placebo in a 12-week, multicenter, parallel, double-blind, placebo-controlled trial. Dual primary end points were change in average number of toilet voids and change in urgency incontinence episodes per 24 hours. Secondary efficacy variables were change in average volume per void, voiding urgency severity, urinations during day and night, time to onset of action, and change in Incontinence Impact Questionnaire score. By week 12, trospium significantly decreased average frequency of toilet voids per 24 hours (-2.37) and urgency incontinence episodes 59% compared with placebo (-1.29 ; 44%). It significantly increased average volume per void (32 mL; placebo, 7.7 mL), and decreased average urgency severity and daytime frequency. All effects occurred by week 1 and all were sustained throughout the study. Nocturnal frequency decreased significantly by week 4 (-0.43 ; placebo, -0.17), and Incontinence Impact Questionnaire scores improved at week 12. Trospium was well tolerated. The most common side effects were dry mouth (21.8%; placebo 6.5%), constipation (9.5%; placebo 3.8%), and headache (6.5%; placebo 4.6%). In a large U.S. multicenter trial with the same design and including 658 patients with OAB, **Rudy and colleagues (2006)** confirmed the data by **Zinner and colleagues (2004)**, with respect to both efficacy and adverse effects.

Dose escalation seems to improve therapeutic efficacy. In a 12-week, randomized, double-blind, phase IIIb study including 1658 patients with urinary frequency plus urgency incontinence, patients received trospium chloride 15 mg tid ($n = 828$) or 2.5 mg oxybutynin hydrochloride tid ($n = 830$). After 4 weeks, daily doses were doubled and not readjusted in 29.2% (242 of 828) of patients in the trospium group and in 23.3% (193 of 830) in the oxybutynin group, until the end of treatment. At study end, there were no relevant differences between the "dose adjustment" subgroups and the respective "no dose adjustment" subgroups (trospium, $P = .249$; oxybutynin, $P = .349$). After dose escalation, worsening of dry mouth was higher in both dose-adjusted subgroups compared with the respective "no dose adjustment" subgroups ($P < .001$). Worsening of dry mouth was lower in the trospium groups than in the oxybutynin groups (**Bödeker et al, 2010**).

An ER formulation of trospium allowing once-daily administration has been introduced (**Silver et al, 2010**), and its effects have been tested in controlled trials (**Staskin et al, 2007**; **Dmochowski et al, 2008**; **Chancellor et al, 2010**; **MacDiarmid et al, 2011**; **Sand et al, 2011a, 2011b**; **Zinner et al, 2011**). These studies demonstrated similar efficacy as found with previous formulations, but include

experiences in, for example, elderly patients (>75 years), obese patients, and patients who use multiple concomitant medications. The most frequent side effects were dry mouth (12.9%; placebo, 4.6%) and constipation (7.5%; placebo, 1.8%) (**Dmochowski et al, 2008**).

Intravesical application of trospium may be an interesting alternative. **Frölich and colleagues (1998)** performed a randomized, single-blind, placebo-controlled, monocenter clinical trial in 84 patients with urgency or urgency incontinence. Compared with placebo, intravesical trospium produced a significant increase in maximum bladder capacity and a decrease of detrusor pressure accompanied by an increase of residual urine. There was an improvement in uninhibited bladder contractions. No adverse events were reported. It is interesting to note that intravesical trospium does not seem to be absorbed (**Walter et al, 1999**), thus offering an opportunity for treatment with minimal systemic antimuscarinic effects.

Assessment. Trospium has a well-documented effect in OAB and DO, and tolerability and safety seem acceptable (see **Table 79-3**).

Antimuscarinics with "Mixed" Action

Some drugs used for treatment of OAB and DO have been shown to have more than one mechanism of action. They all have a more-or-less pronounced antimuscarinic effect and, in addition, an often poorly defined "direct" action on bladder muscle. For several of these drugs, the antimuscarinic effects can be demonstrated at much lower drug concentrations than the direct action, which may involve blockade of voltage-operated Ca^{2+} channels. Most probably, the clinical effects of these drugs can be explained mainly by an antimuscarinic action. Among the drugs with mixed actions was terodiline, which was withdrawn from the market because it was suspected to cause polymorphic ventricular tachycardia (torsades de pointes) in some patients (**Connolly et al, 1991**; **Stewart et al, 1992**).

Oxybutynin Chloride. Oxybutynin is a tertiary amine that is well absorbed and undergoes extensive upper gastrointestinal and first-pass hepatic metabolism via the cytochrome P450 system (CYP3A4) into multiple metabolites. The primary metabolite, *N*-desethyloxybutynin, has pharmacologic properties similar to those of the parent compound (**Waldeck et al, 1997**) but occurs in much higher concentrations after oral administration (**Hughes et al, 1992**). It has been implicated as the major cause of the troublesome side effect of dry mouth associated with the administration of oxybutynin. It seems reasonable to assume that the effect of oral oxybutynin to a large extent is exerted by the metabolite. The occurrence of an active metabolite may also explain the lack of correlation between plasma concentration of oxybutynin itself and side effects in geriatric patients reported by **Ouslander and colleagues (1988)**. The plasma half-life of the oxybutynin is approximately 2 hours, but with wide interindividual variation (**Douchamps et al, 1988**; **Hughes et al, 1992**).

Oxybutynin has several pharmacologic effects in vitro, some of which seem difficult to relate to its effectiveness in the treatment of DO. It has both an antimuscarinic and a direct muscle relaxant effect, and, in addition, local anesthetic actions. The latter may be of importance when the drug is administered intravesically, but probably play no role when it is given orally. In vitro, oxybutynin was 500 times weaker as a smooth muscle relaxant than as an antimuscarinic agent (**Kachur et al, 1988**). Most probably, when given systemically, oxybutynin acts mainly as an antimuscarinic drug. Oxybutynin has a high affinity for muscarinic receptors in human bladder tissue and effectively blocks carbachol-induced contractions (**Nilvebrant and Sparf, 1988**; **Waldeck et al, 1997**). The drug was shown to have slightly higher affinity for muscarinic M_1 and M_3 receptors than for M_2 receptors (**Nilvebrant and Sparf, 1986**; **Norhona-Blob and Kachur, 1991**), but the clinical significance of this is unclear.

The IR form of oxybutynin (OXY-IR) is recognized for its efficacy, and most of the newer antimuscarinic agents have been compared with it once efficacy over placebo has been determined. In general, the new formulations of oxybutynin and other antimuscarinic

agents offer patients efficacy roughly equivalent to that of OXY-IR, and the advantage of the newer formulations lies in improved dosage schedules and side effect profile (Appell et al, 2001; Dmochowski et al, 2002; Diokno et al, 2003). An OXY-ER once-daily oral formulation and an oxybutynin transdermal delivery system (OXY-TDS) are available. OXY-TDS offers a twice-weekly dosage regimen and the potential for improved patient compliance and tolerability. Some of the available formulations of oxybutynin were overviewed by McCrery and Appell (2006).

Immediate-Release Oxybutynin. Several controlled studies have shown that OXY-IR is effective in controlling DO, including NDO (Yarker et al, 1995; Andersson and Chapple, 2001). The recommended oral dose of the IR form is 5 mg three times daily or four times daily, even if lower doses have been used. Thüroff and colleagues (1998) summarized 15 randomized controlled studies on a total of 476 patients treated with oxybutynin. The mean decrease in incontinence was recorded as 52% and the mean reduction in frequency per 24 hours was 33% (data on placebo not presented). The overall “subjective improvement” rate was reported as 74% (range 61% to 100%). The mean percent of patients reporting an adverse effect was 70% (range 17% to 93%). Oxybutynin, 7.5 to 15 mg/day, significantly improved QoL of patients with OAB in a large open multicenter trial. In this study, patient compliance was 97% and side effects, mainly dry mouth, were reported by only 8% of the patients (Amarenco et al, 1998). In 75 nursing home residents, Ouslander and colleagues (1995) found that oxybutynin did not add to the clinical effectiveness of prompted voiding in a placebo-controlled, double-blind, crossover trial. On the other hand, in another controlled trial in 57 elderly subjects, oxybutynin with BT was found to be superior to BT alone (Szonyi et al, 1995).

Several open studies in patients with spinal cord injuries suggested that oxybutynin, given orally or intravesically, can be of therapeutic benefit (Kim et al, 1996; Szollar and Lee, 1996).

The therapeutic effect of OXY-IR on DO is associated with a high incidence of side effects (up to 80% with oral administration). These are typically antimuscarinic in nature (dry mouth, constipation, drowsiness, blurred vision) and are often dose limiting (Baigrie et al, 1988; Jonville et al, 1992). The effects of oxybutynin on the ECG were studied in elderly patients with UI (Hussain et al, 1996); no changes were found. It cannot be excluded that the commonly recommended dose of 5 mg \times 3 is unnecessarily high in some patients, and that a starting dose of 2.5 mg \times 2 with subsequent dose titration would reduce the number of adverse effects (Amarenco et al, 1998).

Extended Release Oxybutynin. The OXY-ER formulation was developed to decrease liver metabolite formation of desethyloxybutynin (DEO) with the presumption that it would result in decreased side effects, especially dry mouth, and improve patient compliance with remaining on oxybutynin therapy (Arisco et al, 2009). The formulation uses an osmotic system to release the drug at a controlled rate over 24 hours distally primarily into the large intestine where absorption is not subject to first-pass metabolism in the liver. This reduction in metabolism is meant to improve the rate of dry mouth complaints when compared with OXY-IR. DEO is still formed through the hepatic cytochrome P450 enzymes, but clinical trials have indeed demonstrated improved dry mouth rates compared with OXY-IR (Appell et al, 2003). Salivary output studies have also been interesting. Two hours after administration of OXY-IR or TOLT-IR, salivary production decreased markedly and then gradually returned to normal. With OXY-ER, however, salivary output was maintained at predose levels throughout the day (Chancellor et al, 2001).

The effects of OXY-ER have been well documented (Siddiqui et al, 2004). In the OBJECT study (Appell et al, 2001), the efficacy and tolerability of 10-mg OXY-ER was compared with a twice-daily 2-mg dose of TOLT-IR. OXY-ER was statistically more effective than the TOLT-IR in weekly urgency incontinence episodes (OXY-ER from 25.6% to 6.1%; TOLT-IR 24.1% to 7.8%), total incontinence (OXY-ER from 28.6% to 7.1%; TOLT-IR 27.0% to 9.3%), and frequency (OXY-ER from 91.8% to 67.1%; TOLT-IR 91.6% to 71.5%),

and both medications were equally well tolerated. The basic study was repeated as the OPERA study (Diokno et al, 2003) with the difference that this study was a direct comparison of the two ER forms, OXY-ER (10 mg) and TOLT-ER (4 mg) and the results were quite different. In this study there was no significant difference in efficacy for the primary end point of urgency incontinence; however, TOLT-ER had a statistically lower incidence of dry mouth. OXY-ER was statistically better at 10 mg than TOLT-ER 4 mg in only the reduction of the rate of urinary frequency. These studies made it clear that in comparative studies, IR entities of one drug should no longer be compared with ER entities of the other.

Greater reductions in urgency and total incontinence have been reported in patients treated in dose-escalation studies with OXY-ER. In two randomized studies, the efficacy and tolerability of OXY-ER were compared with those of OXY-IR. In the 1999 study (Anderson et al, 1999), 105 patients with urgency or mixed incontinence were randomized to receive 5 to 30 mg of OXY-ER once daily or 5 mg of OXY-IR one to four times per day. Dose titrations began at 5 mg, and the dose was increased every 4 to 7 days until one of three end points was achieved. These were (1) the patient reported no urgency incontinence during the final 2 days of the dosage period; (2) the maximum tolerable dose was reached; or (3) the maximum allowable dose (30 mg for OXY-ER or 20 mg for OXY-IR) was reached. The mean percent reduction in weekly urgency and total incontinence episodes was statistically similar between OXY-ER and OXY-IR, but dry mouth was reported statistically more often with OXY-IR. In the 2000 study (Versi et al, 2000), 226 patients were randomized between OXY-ER and OXY-IR with weekly increments of 5 mg daily up to 20 mg daily. As in the 1999 study, OXY-ER again achieved a greater than 80% reduction in urgency and total incontinence episodes, and a significant percentage of patients became dry. A negative aspect of these studies is that there were no naive patients included; all patients were known responders to oxybutynin. Similar efficacy results have been achieved, however, with OXY-ER in a treatment-naive population (Gleason et al, 1999).

In an RCT comparing different daily doses of oxybutynin (5, 10, and 15 mg), Corcos and colleagues (2006) found a significant dose-response relationship for both urgency incontinence episodes and dry mouth. The greatest satisfaction was with 15 mg of oxybutynin per day.

In a multicenter, prospective, observational, flexible-dosing Korean study, Yoo and colleagues (2012) investigated the prescription pattern and dose distribution of OXY-ER in patients with the OAB syndrome in actual clinical practice. The dose for each patient was adjusted after discussions of efficacy and tolerability between doctor and patient, over a 12-week treatment period. Efficacy was measured by administering the Primary OAB Symptom Questionnaire (POSQ) before and after treatment. Patients were also administered a patient perception of treatment benefit (PPTB) questionnaire at the end of the study. Of the 809 patients enrolled, 590 (73.2%) continued to take study medication for 12 weeks. Most patients were prescribed 5 to 10 mg of oxybutynin ER per day as both starting and maintenance doses, with a dose escalation rate of only 14.9%. All OAB symptoms evaluated by the POSQ were improved; 94.1% of patients reported benefits from treatment, and 89.3% were satisfied.

Transdermal Oxybutynin. Transdermal delivery also alters oxybutynin metabolism, reducing DEO production to an even greater extent than OXY-ER. A study (Davila et al, 2001) comparing OXY-TDS with OXY-IR demonstrated a statistically equivalent reduction in daily incontinence episodes (from 7.3 to 2.3 [66%] for OXY-TDS; and 7.4 to 2.6 [72%] for OXY-IR), but much less dry mouth (38% for OXY-TDS and 94% for OXY-IR). In another study (Dmochowski et al, 2002) the 3.9-mg daily-dose patch significantly (vs. placebo) reduced the mean number of daily incontinence episodes (from 4.7 to 1.9; placebo from 5.0 to 2.9) while reducing average daily urinary frequency, confirmed by an increased average voided volume (from 165 to 198 mL; placebo from 175 to 182 mL). Furthermore, dry mouth rate was similar to placebo (7% vs. 8.3%). In a third study (Dmochowski et al, 2003b) OXY-TDS

was compared not only with placebo but with TOLT-ER. Both drugs equivalently and significantly reduced daily incontinence episodes and increased the average voided volume, but TOLT-ER was associated with a significantly higher rate of antimuscarinic adverse events. The primary adverse event for OXY-TDS was application site reaction pruritus in 14% and erythema in 8.3%, with nearly 9% feeling that the reactions were severe enough to withdraw from the study despite the lack of systemic problems.

The pharmacokinetics and adverse effect dynamics of OXY-TDS (3.9 mg/day) and OXY-ER (10 mg/day) were compared in healthy subjects in a randomized, two-way crossover study (Appell et al, 2003). Multiple blood and saliva samples were collected and pharmacokinetic parameters and total salivary output were assessed. OXY-TDS administration resulted in greater systemic availability and minimal metabolism to DEO compared with OXY-ER, which resulted in greater salivary output in OXY-TDS patients and less dry mouth symptomatology than when taking OXY-ER.

Dmochowski and colleagues (2005), analyzing the combined results of two RCTs, concluded that transdermal oxybutynin was shown to be efficacious and well tolerated. The most common systemic side effect was dry mouth (7.0% vs. placebo 5.3%). Application site erythema occurred in 7% and pruritus in 16.1%. Also Cartwright and Cardozo (2007), reviewing published and presented data, concluded that transdermal oxybutynin has a good balance between efficacy and tolerability with a rate of systemic antimuscarinic side effects that is lower than with oral antimuscarinics; however, this benefit was offset by the rate of local skin reaction. The reviews of Sahai and colleagues (2008) and Staskin and Salvatore (2010) largely confirmed these conclusions, which also have been supported by further studies (Cartwright et al, 2011).

Oxybutynin Topical Gel. Given the efficacy and tolerability of the transdermal application, limited only by skin site reactions, a gel formulation was developed. Oxybutynin topical gel (OTG) was approved by the U.S. Food and Drug Administration (FDA) in January 2009. OTG is applied once daily to the abdomen, thigh, shoulder, or upper arm area (Staskin et al, 2009). The 1-g application dose delivers approximately 4 mg of drug to the circulation, with stable plasma concentrations and a "favorable" *N*-desethyloxybutynin metabolite-oxybutynin ratio, believed to minimize antimuscarinic side effects (Staskin and Robinson, 2009). In a multicenter RCT, 789 patients (89% women) with urgency-predominant incontinence were assigned to OTG or placebo once daily for 12 weeks (Staskin et al, 2009). The mean number of urgency episodes, as recorded by 3-day voiding diary, was reduced by 3.0 episodes per day versus 2.5 in the placebo arm ($P < .0001$). Urinary frequency decreased by 2.7 episodes per day, and voided volume increased by 21 mL (vs. 2.0 episodes [$P = .0017$] and 3.8 mL [$P = .0018$], respectively, in the placebo group). Dry mouth was reported in 6.9% of the treatment group versus 2.8% of the placebo group. Skin reaction at the application site was reported in 5.4% of the treatment group versus 1.0% in the placebo arm. It was felt that improved skin tolerability of the gel over the OXY transdermal patch delivery system was secondary to lack of adhesive and skin occlusion. The gel dries rapidly on application and leaves no residue; person-to-person transference via skin contact is largely eliminated if clothing is worn over the application site (Dmochowski et al, 2011). The evolution of the transdermal gel allows greater patient tolerability and improved compliance. This was confirmed by Sand and colleagues (2012a), who showed that in 704 women with OAB, OTG significantly reduced the number (mean \pm standard deviation [SD]) of daily incontinence episodes (OTG, -3.0 ± 2.8 episodes; placebo, -2.5 ± 3.0 episodes), reduced urinary frequency, increased voided volume, and improved select health-related quality-of-life domains versus placebo. Dry mouth was the only drug-related adverse event significantly more common with OTG (7.4%) than with placebo (2.8%).

Other Administration Forms. Rectal administration (Collas and Malone-Lee, 1997) was reported to have fewer adverse effects than the conventional tablets.

Administered intravesically, oxybutynin has in several studies been demonstrated to increase bladder capacity and produce clinical

improvement with few side effects, both in neurogenic and in other types of DO, and in both children and adults (Lose and Norgaard, 2001; Fader et al, 2007; George et al, 2007; Guerra et al, 2008), although adverse effects may occur (Kasabian et al, 1994; Palmer et al, 1997).

Effects on Cognition. Several studies have documented the possibility that oxybutynin may have negative effects on cognitive functions, particularly in the elderly population but also in children (see, e.g., Kay et al, 2006; Klausner and Steers, 2007; Kay and Ebinger, 2008). This factor should be taken into consideration when prescribing the drug.

Assessment. Oxybutynin has well-documented efficacy in the treatment of OAB and DO (see Table 79-3). Despite the adverse effect profile, it is still an established therapeutic option.

Propiverine Hydrochloride. Several aspects of the preclinical, pharmacokinetic, and clinical effects of propiverine have been reviewed by Madersbacher and Murz (2001). The drug is rapidly absorbed (T_{max} 2 hours) but has a high first-pass metabolism, and its biologic availability is about 50%. Propiverine is an inducer of hepatic cytochrome P450 enzymes in rats in doses about 100 times above the therapeutic doses in humans (Walter et al, 2003). Several active metabolites that quantitatively and qualitatively differ from the mother compound are formed (Haustein et al, 1988; Müller et al, 1993; Wuest et al, 2006; Sugiyama et al, 2008; Zhu et al, 2008). Most probably these metabolites contribute to the clinical effects of the drug, but their individual contributions have not been clarified (Michel and Hegde, 2006). The half-life of propiverine itself is about 11 to 14 hours. An ER preparation was shown to be effective (Jünemann et al, 2006; May et al, 2008). Oral absorption of propiverine is site dependent and influenced by dosage form and circadian time-dependent elimination processes (May et al, 2008).

Propiverine has combined antimuscarinic and calcium antagonistic actions (Haruno, 1992; Tokuno et al, 1993). The importance of the calcium antagonistic component for the drug's clinical effects has not been established. Propiverine has no selectivity for muscarinic receptor subtypes. The effects of propiverine on cardiac ion channels and action potentials were investigated by Christ and colleagues (2008). Propiverine blocked, in a concentration-dependent manner, hERG channels expressed in HEK293 cells, as well as native I(Kr) current in ventricular myocytes of guinea pig. However, action potential duration was not prolonged in guinea pig and human ventricular tissue, and the investigators concluded that their results did not provide evidence for an enhanced cardiovascular safety risk with the drug.

Propiverine has been shown to have beneficial effects in patients with DO in several investigations. Thüroff and colleagues (1998) analyzed nine randomized studies on a total of 230 patients and found a 17% reduction in micturitions per 24 hours, a 64-mL increase in bladder capacity, and a 77% (range 33% to 80%) subjective improvement. Side effects were found in 14% (range 8% to 42%). In patients with NDO, controlled clinical trials have demonstrated propiverine's superiority over placebo (Stöhrer et al, 1999). Propiverine also increased bladder capacity and decreased maximum detrusor contractions. Controlled trials comparing propiverine, flavoxate, and placebo (Wehnert et al, 1989) and propiverine, oxybutynin, and placebo (Wehnert et al, 1992; Madersbacher et al, 1999) have confirmed the efficacy of propiverine, and suggested that the drug may have equal efficacy and fewer side effects than oxybutynin. In a comparative RCT including 131 patients with NDO, propiverine and oxybutynin were compared (Stöhrer et al, 2007). The drugs were found to be equally effective in increasing bladder capacity and lowering bladder pressure. Propiverine caused a significantly lower frequency of dry mouth than oxybutynin.

Also in children and adolescents with NDO, propiverine was found to be effective (Grigoleit et al, 2006; Schulte-Baukloh et al, 2006), with a low incidence rate of adverse events ($<1.5\%$) (Grigoleit et al, 2006). A randomized, double-blind, placebo-controlled trial with parallel-group design in children aged 5 to 10 years was performed by Marschall-Kehrel and colleagues (2009). Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. Decrease in voiding frequency per day was the primary efficacy

parameter; secondary end points included voided volume and incontinence episodes. There was a significant decrease in voiding frequency episodes for propiverine versus placebo. Superiority could also be demonstrated for voided volume and incontinence episodes per day. Propiverine was well tolerated; 23% of patients reported side effects for propiverine and 20% for placebo.

In a randomized, double-blind, multicenter clinical trial, patients with IDO were treated with 15 mg of propiverine twice daily or 2 mg of TOLT-IR twice daily over a period of 28 days (Jünemann et al, 2005). The maximum cystometric capacity was determined at baseline and after 4 weeks of therapy. The difference of both values was used as the primary end point. Secondary end points were voided volume per micturition, evaluation of efficacy (by the investigator), tolerability, PVR urine, and QoL. It was found that the mean maximum cystometric capacity increased significantly ($P < .01$) in both groups. The volume at first urgency and the frequency and volume chart parameters also showed relevant improvements during treatment. The most common adverse event, dry mouth, occurred in 20 patients in the propiverine group and in 19 patients in the tolterodine group. The scores for QoL improved comparably in both groups.

Madersbacher and colleagues (1999) compared the tolerability and efficacy of propiverine (15 mg three times daily), oxybutynin (5 mg twice daily), and placebo in 366 patients with urgency and urgency incontinence in a randomized, double-blind, placebo-controlled clinical trial. Urodynamic efficacy of propiverine was judged similar to that of oxybutynin, but the incidence of dry mouth and the severity of dry mouth were judged to be less with propiverine than with oxybutynin. Dorschner and colleagues (2000) investigated in a double-blind, multicenter, placebo-controlled, randomized study the efficacy and cardiac safety of propiverine in 98 elderly patients (mean age 68 years) with urgency, urgency incontinence, or mixed urgency-stress incontinence. After a 2-week placebo run-in period, the patients received propiverine (15 mg three times daily) or placebo (three times daily) for 4 weeks. Propiverine caused a significant reduction of the micturition frequency (from 8.7 to 6.5) and a significant decrease in episodes of incontinence (from 0.9 to 0.3 per day). The incidence of adverse events was very low (2% dryness of the mouth under propiverine—2 out of 49 patients). Resting and ambulatory ECGs indicated no significant changes. The cardiac safety of propiverine was further studied by Donath and colleagues (2011) in two comprehensively designed monocentric ECG studies (including 24 healthy women, followed by a second study on 24 male patients with coronary heart disease (CHD) and a pathologic Pardee Q wave on the ECG). Both studies were placebo controlled and compared the effects of single-dose (30 mg *sid*) and multiple-dose (15 mg *tid*) administration of propiverine hydrochloride in a crossover design over 6 and 13 days, respectively. They were performed to investigate the influence of propiverine hydrochloride and its main metabolite, propiverine *N*-oxide, on cardiac function with regard to QTc prolongation, QTc dispersion, and T-wave shape. No negative effects on cardiac safety could be demonstrated.

Abrams and colleagues (2006b) compared the effects of propiverine and oxybutynin on ambulatory urodynamic monitoring (AUM) parameters, safety, and tolerability in OAB patients. Seventy-seven patients received two of the following treatments during two 2-week periods: propiverine 20 mg once daily, propiverine 15 mg three times daily, oxybutynin 5 mg three times daily, and placebo. The researchers found that oxybutynin 15 mg was more effective than propiverine 20 mg in reducing symptomatic and asymptomatic involuntary detrusor contractions in ambulatory patients. Oxybutynin had a higher rate of dry mouth, and propiverine had a more pronounced effect on gastrointestinal, cardiovascular, and visual function.

Yamaguchi and colleagues (2007) performed a multicenter, 12-week, double-blind phase III trial in Japanese men and women with OAB (1593 patients were randomized and 1584 were treated), comparing solifenacin 5 or 10 mg, propiverine 20 mg, and placebo. Changes at end point in number of voids per 24 hours, urgency, incontinence, urgency incontinence and nocturia episodes, volume

voided per void, restoration of continence, and QoL were examined. It was found that at end point there were greater reductions in mean (SD) voids per 24 hours with all drug regimens than with placebo. All active treatments improved the volume voided and QoL versus placebo; solifenacin 10 mg reduced nocturia episodes and significantly improved urgency episodes and volume voided versus propiverine 20 mg, and solifenacin 5 mg caused less dry mouth. Solifenacin 10 mg caused more dry mouth and constipation than propiverine 20 mg. Wada and colleagues (2011) performed a prospective nonrandomized crossover study of female OAB patients, assigned alternately to treatment with propiverine (20 mg) for 8 weeks then solifenacin (5 mg) for 8 weeks or solifenacin for 8 weeks then propiverine for 8 weeks. At baseline, 8th week, and 16th week, symptoms were assessed using OAB Symptom Score. Of the 121 patients enrolled, 83 were analyzed. Both drugs were effective. Urgency was further improved after switching from propiverine to solifenacin, but not after switching from solifenacin to propiverine. Solifenacin was better tolerated than propiverine.

In another multicenter, prospective, parallel, double-blind, placebo-controlled trial, Lee and colleagues (2010) studied the effects of 30 mg of propiverine per day in 264 OAB patients (mean age 52.2 years), 221 of whom had efficacy data available from baseline and at least one on-treatment visit with greater than 75% compliance. The study was focused on improving urgency. Overall, among patients treated with propiverine, 39% rated their treatment as providing “much benefit,” compared with 15% in the placebo group. Adverse events reported by 32 (22.5%) and 10 (12.7%) patients in the propiverine and placebo group were all tolerable.

Masumori and colleagues (2011) examined prospectively the efficacy and safety of propiverine in patients with OAB who responded poorly to previous treatment with solifenacin, tolterodine, or imidafenacin. Of 73 patients enrolled (29 men and 44 women, median age 71 years), 52 completed the protocol treatment. The OAB Symptom Score was significantly improved by propiverine treatment. The scores of OAB symptoms (nighttime frequency, urgency, and urge incontinence) except daytime frequency also improved significantly. No increase in PVR was observed. The most frequent adverse event was dry mouth (13.7%), followed by constipation (6.8%).

In a noncontrolled study in patients with wet OAB, the efficacy of propiverine on symptoms and QoL was confirmed (Komatsu et al, 2009).

Assessment. Propiverine has a documented beneficial effect in the treatment of OAB and DO (see Table 79-3) and seems to have an acceptable side effect profile. It is not approved for use in the United States.

Flavoxate Hydrochloride. Flavoxate is often discussed as a drug with mixed actions; however, its main mechanism of action may not be antimuscarinic. Flavoxate is well absorbed, and oral bioavailability appeared to be close to 100% (Guay, 2003). The drug is extensively metabolized and plasma half-life was found to be 3.5 hours (Sheu et al, 2001). Its main metabolite (3-methylflavone-8-carboxylic acid [MFCA]) has been shown to have low pharmacologic activity (Cazzulani et al, 1988; Caine et al, 1991). The main mechanism of flavoxate's effect on smooth muscle has not been established. The drug has been found to possess a moderate calcium antagonistic activity, to have the ability to inhibit phosphodiesterase (PDE), and to have local anesthetic properties; no antimuscarinic effect was found (Guarneri et al, 1994). Uckert and colleagues (2000), on the other hand, found that in strips of human bladder, the potency of flavoxate to reverse contraction induced by muscarinic receptor stimulation and by electrical field stimulation was comparable. It has been suggested that pertussis toxin-sensitive G proteins in the brain are involved in the flavoxate-induced suppression of the micturition reflex, because intracerebroventricularly or intrathecally administered flavoxate abolished isovolumetric rhythmic bladder contractions in anesthetized rats (Oka et al, 1996).

The clinical effects of flavoxate in patients with DO and frequency, urgency, and incontinence have been studied in both open and controlled investigations, but with varying rates of success (Ruffman, 1988). Stanton (1973) compared emeprenium bromide

and flavoxate in a double-blind crossover study of patients with DO and reported improvement rates of 83% and 66% after flavoxate or emepronium bromide, respectively, both administered at 200 mg three times daily. In another double-blind crossover study comparing flavoxate 1200 mg/day with oxybutynin 15 mg/day in 41 women with idiopathic motor or sensory urgency, and using both clinical and urodynamic criteria, [Milani and colleagues \(1993\)](#) found both drugs effective. No difference in efficacy was found between them, but flavoxate had fewer and milder side effects. Other investigators comparing the effects of flavoxate with those of placebo have not been able to show any beneficial effect of flavoxate at doses up to 400 mg three times daily ([Briggs et al, 1980](#); [Chapple et al, 1990](#); [Dahm et al, 1995](#)). In general, few side effects have been reported during treatment with flavoxate. On the other hand, its efficacy compared with other therapeutic alternatives is not well documented (see [Table 79-3](#)).

Assessment. No RCTs seem to have been performed with flavoxate during the last decade. The scarcity of evidence regarding documented clinical efficacy should be considered before use of the drug.

KEY POINTS: ANTIMUSCARINIC THERAPY

- Drugs can alter LUT function by acting at any point along the afferent or efferent limb of innervation by reception activation or blockade, or by affecting the concentration of the neural transmitter at an activation site, or by stimulating or inhibiting signal transduction mechanisms. Functionally, these actions can be divided into those that facilitate bladder filling or urine storage versus those that facilitate bladder emptying or voiding. Furthermore, these actions can be subdivided into those that primarily affect the bladder or outlet. Some drugs will have an effect on both. Atropine and atropine-like agents that inhibit muscarinic receptors are the most commonly used agents to inhibit involuntary contractions. They also act to maintain low bladder tone during filling with a consequent decrease in filling and storage symptoms that are unrelated to the occurrence of an involuntary contraction. They do so primarily by the inhibition of muscarinic receptors, located on detrusor muscle cells, urothelial cells, suburothelial nerves, and interstitial cells. There are five pharmacologically defined muscarinic receptors; the M_2 receptor is the most common in the human bladder, but the M_3 receptor is the most important for contraction. As opposed to the traditional view that antimuscarinics in the usual administered clinical doses act by blocking the muscarinic receptors on the detrusor muscle, they appear to act mainly during the storage phase, decreasing urgency and increasing bladder capacity. In the dosage range used for treatment of the symptoms of OAB or DO, there is little evidence for a significant reduction of the voiding contraction. Higher doses can and will produce a reduction of the voiding contraction.
- In general, drug therapy for LUT dysfunction is hindered by *uroselectivity*, a term that originated with Karl-Erik Andersson.
- Antimuscarinics are of significant clinical benefit in the treatment of OAB and related symptoms. There are numerous such agents available, and the pharmacologic profiles of each drug and their individual characteristics differ. None, however, is ideal as a first-line treatment for all patients with OAB or DO.
- Persistence with current antimuscarinic agents for such treatment is low, owing to a combination of relative lack of efficacy and adverse effects.
- Some drugs are labelled as primarily antimuscarinic but with a mixed action, meaning there is often a poorly defined direction of action bladder smooth muscle; however, most probably the clinical effects of such drugs can be explained primarily by the antimuscarinic action.

Drugs Acting on Membrane Channels

Calcium Antagonists. Activation of detrusor muscle, through both muscarinic-receptor and NANC pathways, seems to require influx of extracellular Ca^{2+} through Ca^{2+} channels as well as via mobilization of intracellular Ca^{2+} ([Andersson, 1993](#); [Andersson and Arner, 2004](#)). The influx of extracellular calcium can be blocked by calcium antagonists, blocking L-type Ca^{2+} channels, and theoretically this would be an attractive way of inhibiting DO and regulating detrusor smooth muscle tone ([Berridge, 2008](#)). Two major groups of calcium channels include the voltage-gated ([Catterall et al, 2003](#)) and the store-operated channels ([Leung et al, 2008](#)). Although both can contribute to the maintenance of smooth muscle tone in general, store-operated calcium channels apparently contribute only to a limited, if any, extent to the regulation of bladder smooth muscle tone ([Schneider et al, 2004a, 2004b](#)). On the other hand, various types of voltage-operated calcium channels have been implicated in the regulation of bladder smooth muscle including Q-type ([Frew and Lundy, 1995](#)) and L-type channels ([Wuest et al, 2007](#)). The latter appear to be of particular importance because inhibitors of L-type channels have repeatedly been shown to inhibit bladder contraction in vitro with tissue from multiple mammalian species, including humans ([Frazier et al, 2008](#)). However, the relative importance of L-type channels may be somewhat less in humans than in other mammalian species ([Wuest et al, 2007](#)). In confirmation of the role of L-type calcium channels, it has been shown that KO mice lacking a crucial subunit of this channel exhibit a markedly impaired bladder contractility ([Wegener et al, 2004](#)).

Although these in vitro data suggest a possible role for calcium channel inhibitors, particularly those of L-type channels, in the treatment of DO and incontinence, only limited clinical studies are available in this regard. One urodynamic study compared the effects of intravesical instillation of the calcium channel inhibitor verapamil, the muscarinic-receptor antagonists oxybutynin and trospium, and placebo in patients with urgency or urgency incontinence. Whereas the two muscarinic-receptor antagonists significantly increased bladder capacity, verapamil treatment was not associated with relevant changes in bladder function ([Fröhlich et al, 1998](#)). In a clinical study of limited size, the calcium channel inhibitor nimodipine (30 mg/day) did not significantly improve the number of incontinence episodes as compared with placebo ([Naglie et al, 2002](#)). It should be noted that despite a long-standing and widespread use of calcium channel inhibitors in the treatment of cardiovascular disease, there are no major reports on impaired bladder contractility as a side effect of such treatment. The reasons for the discrepancy between the promising in vitro data and the lack of clinical data are not fully clear, but they may relate to pharmacokinetic properties of the currently used drugs, which may insufficiently either reach or penetrate bladder tissue in therapeutically administered doses. At present, there is no clinical evidence to support a possible use of calcium channel inhibitors in the treatment of bladder dysfunction (see [Table 79-3](#)).

Potassium Channel Openers. Potassium channels contribute to the membrane potential of smooth muscle cells and hence to the regulation of smooth muscle tone. Numerous types of potassium channels exist in the bladder ([Gutman et al, 2003](#); [Petkov, 2011](#)). With regard to bladder function, ATP-dependent (K_{ATP}) and big calcium-activated (BK_{Ca}) channels have been studied most intensively. The BK_{Ca} channels also appear to be important physiologically because their activation can cause hyperpolarization of bladder smooth muscle cells, and by this mechanism they can contribute to the relaxation of bladder smooth muscle by, for example, β -AR agonists ([Frazier et al, 2008](#)). Openers of both K_{ATP} ([Howe et al, 1995](#); [Hu and Kim, 1997](#); [Martin et al, 1997](#)) and BK_{Ca} channels ([Hu and Kim, 1997](#); [Sheldon et al, 1997](#)) have been shown to induce bladder smooth muscle relaxation in various mammalian species, but the density of some types of potassium channels may differ markedly among species. Some potassium channel openers have also been shown to suppress nonvoiding detrusor contractions in vivo in animal models of DO ([Howe et al, 1995](#); [Martin et al,](#)

1997; Tanaka et al, 2003), and this also includes activators of the KCNQ type of potassium channels (Streng et al, 2004). Although potassium channel openers are believed to mainly act directly on smooth muscle cells (Gopalakrishnan and Shieh, 2004; Petkov, 2011), they may also at least in part affect bladder function by modulating the activity of afferent neurones (Tanaka et al, 2003).

Although the aforementioned data demonstrate the potential of potassium channel openers to inhibit nonvoiding detrusor contractions, these channels are expressed not only in bladder, but also in, for example, vascular smooth muscle. Therefore potassium channel openers may also affect cardiovascular function, and in effective doses may considerably lower blood pressure (Howe et al, 1995; Shieh et al, 2007). Whereas some compounds of this class have a certain degree of selectivity for the bladder as compared with the cardiovascular system, it remains unclear whether the degree of selectivity offers a sufficiently large therapeutic window for clinical use. This consideration has led to a considerable hesitancy to study potassium channel openers in OAB patients. Nevertheless, one randomized, placebo-controlled clinical study on the K_{ATP} opener ZD0947 has been reported (Chapple et al, 2006). ZD0947 at the chosen dose did not lower blood pressure or cause adverse events typical for a vasodilating drug, but it also failed to achieve superiority relative to placebo for the treatment of OAB symptoms. Therefore, despite promising preclinical efficacy data, potassium channel openers at present are not a therapeutic option and may never become one owing to a lack of selectivity for bladder over cardiovascular tissues (see Table 79-3).

Another way to use potassium channels to normalize bladder function was suggested by Christ and colleagues (2001) in a rat model of detrusor hyperactivity. They injected “naked” hSlo/pCDNA3 (maxiK channel) into the bladder and found a significant amelioration of the hyperactivity. Whether this principle can be therapeutically useful in humans is currently under investigation.

α -Adrenoceptor Antagonists

It is well documented that α_1 -AR antagonists can ameliorate LUTS in men (Andersson, 2002b; Michel, 2010; McVary et al, 2011; Lepor et al, 2012; Ishizuka et al, 2013; Oelke et al, 2013; Yuan et al, 2013). Currently used α_1 -AR antagonists are considered effective for treatment of both storage and voiding symptoms in men with LUTS associated with or suggestive of benign prostatic hyperplasia (BPH) (Lepor et al, 2012; Soler et al, 2013). However, in a study in which tamsulosin was given alone or together with tolterodine to patients with male LUTS and OAB symptoms, monotherapy with the drug was not effective (Kaplan et al, 2006). Doxazosin monotherapy resulted in only minimal effects in International Prostate Symptom Score (IPSS) storage subscore and urgency episodes and no improvement in patient perception of bladder condition (Lee et al, 2011).

A pivotal question is whether better efficacy and/or tolerability can be achieved by highly subtype-selective drugs than with the commonly used alternatives. α_1 -ARs include three receptor subtypes, α_{1A} , α_{1B} , and α_{1D} , that are structurally and pharmacologically distinct and have different tissue distributions (Andersson and Gratzke, 2007; Yamada and Ito, 2011; Nishimune et al, 2012). α_{1A} -ARs are the predominant subtype in the human prostate, where they mediate smooth muscle contraction. A fourth subtype, α_{1L} , also found in human prostate, is derived from the same gene as the α_{1A} subtype, but α_{1L} and α_{1A} receptors have different pharmacologic properties and bind some α -AR antagonists with different affinities. The precise structural relationship between the two subtypes remains to be elucidated. Selectivity for α_{1B} -AR has been considered disadvantageous from a cardiovascular point of view (Schwinn et al, 2004; Schwinn and Roehrborn, 2008). Kojima and colleagues (2008) studied the expression of α_1 -AR in the transitional zone of prostates from 55 patients with BPH, comparing patients treated with tamsulosin, presumed to block α_{1A} -ARs, and naftopidil, presumed to block α_{1D} -ARs. However, the selectivity of

naftopidil for α_{1D} -ARs versus α_{1A} -ARs is modest (Take et al, 1998), and its use as a tool to differentiate among α_1 -AR subtypes is questionable. Nevertheless, the tamsulosin and naftopidil groups were classified as α_{1A} -AR dominant (22 and 12 patients) and α_{1D} -AR dominant (11 and 16, respectively). The efficacy of tamsulosin and naftopidil differed depending on the dominant expression of the α_1 -AR subtype in the prostate. Tamsulosin was more effective in patients with dominant expression of the α_{1A} -AR subtype, whereas naftopidil was more effective in those with dominant expression of the α_{1D} -AR subtype. In another study, the same group assessed whether there was a direct correlation between the prostatic expression of α_1 -AR subtype mRNA and severity of LUTS or BOO (Kojima et al, 2011). They found no direct correlation between the expression of α_1 -AR subtype mRNA in the prostate and severity of LUTS or BOO, although there was a significant regression of this expression with patient age. Kojima and colleagues (2011) concluded that the expression level of α_1 -AR subtype mRNA in the prostate could be a predictor of the efficacy of subtype-selective α_1 -AR antagonists in patients with BPH and suggested that genetic differences were responsible for the diverse responses to the drugs.

Silodosin (KD-3213), which has a high selectivity for α_{1A} -ARs (Tatemichi et al, 2006a, 2006b; Lepor and Hill, 2010; Yoshida et al, 2011), had clinically good effects on both voiding and storage symptoms in men with BPH (Kawabe et al, 2005; Yoshida et al, 2007; Marks et al, 2009a, 2009b; Morganroth et al, 2010; Chapple et al, 2011; Yoshida et al, 2011). Chapple and colleagues (2011) conducted a multicenter double-blind, placebo- and active-controlled parallel group study comparing silodosin, tamsulosin, and placebo. A total of 1228 men 50 years of age or older with an IPSS of 13 or higher and a urine maximum flow rate (Qmax) greater than 4 and less than or equal to 15 mL/sec were selected at 72 sites in 11 European countries. The patients were entered into a 2-week washout and a 4-week placebo run-in period. A total of 955 patients were randomized (2:2:1) to silodosin 8 mg (n = 381), tamsulosin 0.4 mg (n = 384), or placebo (n = 190) once daily for 12 weeks. Its overall efficacy was not inferior to tamsulosin. Only silodosin showed a significant effect on nocturia over placebo. There was no significant difference among the two α_1 -AR antagonists and the placebo in terms of Qmax. There was also no difference between the two α -AR antagonists for the QoL parameter, although both were better than the placebo. Active treatments were well tolerated, and discontinuation rates resulting from adverse events were low in all groups (2.1%, 1.0%, and 1.6% with silodosin, tamsulosin, and placebo, respectively). The most frequent adverse event with silodosin was a reduced or absent ejaculation during orgasm (14%), a reversible effect as a consequence of the potent and selective α_{1A} -AR antagonism of the drug. The incidence was higher than that observed with tamsulosin (2%); however, only 1.3% of silodosin-treated patients discontinued treatment because of this adverse event. Silodosin treatment improved DO and obstruction grade by decreasing detrusor opening pressure, detrusor pressure at Qmax, BOO Index score, and Schafer obstruction class significantly (Yamanishi et al, 2009). In a different open, nonblinded prospective study, silodosin 8 mg led to a significant increase in bladder capacity at first desire to void with no significant change in maximum cystometric capacity. In the voiding phase, mean detrusor pressure at maximum flow significantly decreased, mean BOO Index score decreased significantly, and obstruction grade as assessed by the Schaefer nomogram improved significantly (Matsukawa et al, 2009).

It thus seems that selective blockade of α_{1A} -ARs is a clinically effective approach, and silodosin is an effective and well-tolerated treatment for the relief of both voiding and storage symptoms in male patients with LUTS, even if treatment is associated with a high incidence of ejaculatory dysfunction.

Interest has also been focused on the α_1 -ARs (α_{1D}), specifically in the bladder (Schwinn et al, 2004; Schwinn and Roehrborn, 2008), on the assumption that these receptors were responsible for storage symptoms. However, the inter-relationship between the α_{1D} -ARs in the human detrusor smooth muscle and the pathophysiology of LUTS is unclear. Naftopidil was shown to

significantly improve the OAB Symptom Score (Sakai et al, 2011) and urgency episodes (Yokoyama et al, 2009). Ikemoto and colleagues (2003) gave tamsulosin and naftopidil to 96 patients with BPH for 8 weeks in a crossover study. Whereas naftopidil monotherapy decreased the IPSS for storage symptoms, tamsulosin monotherapy decreased the IPSS for voiding symptoms. However, this difference (which was suggested to depend on differences in affinity for α_1 -AR subtypes between the drugs) could not be reproduced in a randomized head-to-head comparison between the drugs (Gotoh et al, 2005). Based on available evidence, it therefore cannot be concluded that the α_{1D} -ARs on the detrusor smooth muscle are the main therapeutic target. However, α_{1D} -ARs may have effects on different locations in the bladder aside from the detrusor smooth muscle: the detrusor vasculature, the urothelium, and the afferent and efferent nerve terminals and intramural ganglia (Andersson and Gratzke, 2007; Yamada and Ito, 2011; Moro et al, 2013). The importance and functional role of this observation remain to be established.

In women, treatment of OAB symptoms with α_1 -AR antagonists seems to be ineffective. In an RCT including 364 women with OAB, no effect of tamsulosin versus placebo could be demonstrated (Robinson et al, 2007). On the other hand, voiding symptoms in women with functional outflow obstruction or LUTS were treated (with modest success) with an α_1 -AR antagonist (Kessler et al, 2006; Low et al, 2008). It should be remembered that in women, these drugs may produce stress incontinence (Dwyer and Teele, 1992).

In patients with NDO, treatment with α_1 -AR antagonists was moderately successful (Abrams et al, 2003).

β -Adrenoceptor agonists

Background. The three cloned subtypes of β -ARs (β_1 , β_2 , and β_3) have been identified in the detrusor of most species, including humans (Andersson and Arner, 2004; Michel and Vrydag, 2006). In addition, the human urothelium contains all three receptor subtypes (Otsuka et al, 2008). Studies using real-time reverse transcription polymerase chain reaction (RT-PCR) have revealed a predominant expression of β_3 -AR mRNA in human detrusor muscle (Nomiya and Yamaguchi, 2003; Michel and Vrydag, 2006; Igawa et al, 2010), and the functional evidence for an important role in both normal and neurogenic bladders is convincing (Fujimura et al, 1999; Igawa et al, 1999; Takeda et al, 1999; Morita et al, 2000; Igawa et al, 2001; Biers et al, 2006; Michel and Vrydag, 2006; Leon et al, 2008; Igawa et al, 2010). The human detrusor also contains β_2 -ARs, and most probably both receptors are involved in the physiologic effects (relaxation) of noradrenaline (NA) in this structure (Andersson and Arner, 2004; Michel and Vrydag, 2006; Igawa et al, 2010).

The generally accepted mechanism by which β -ARs induce detrusor relaxation in most species is activation of adenylyl cyclase with the subsequent formation of cAMP. However, there is evidence suggesting that in the bladder, K^+ channels, particularly BK_{Ca} channels, may be more important in β -AR mediated relaxation than cAMP (Hudman et al, 2000; Frazier et al, 2005; Uchida et al, 2005; Frazier et al, 2008). Aizawa and colleagues (2012) showed that the β_3 -AR agonist mirabegron could inhibit filling-induced activity in both mechanosensitive A δ - and C-fiber primary bladder afferents of the rat bladder.

Because β -ARs are present in the urothelium, their possible role in bladder relaxation has been investigated (Murakami et al, 2007; Otsuka et al, 2008). However, to what extent a urothelial signaling pathway contributes in vitro and in vivo to the relaxant effects of β -AR agonists in general, and β_3 -AR agonists specifically, remains to be elucidated.

The in vivo effects of β_3 -AR agonists on bladder function have been studied in several animal models. It has been shown that compared with other agents (including antimuscarinics), β_3 -AR agonists increase bladder capacity with no change in micturition pressure and the residual volume (Fujimura et al, 1999; Woods et al, 2001; Kaidoh et al, 2002; Takeda et al, 2002; Igawa et al, 2010). For example, Hicks and colleagues (2007) studied the effects

of the selective β_3 -AR agonist GW427353 in the anesthetized dog and found that the drug evoked an increase in bladder capacity under conditions of acid-evoked bladder hyperactivity, without affecting voiding.

Clinical Use. The selective β_3 -AR agonist mirabegron has been approved for treatment of OAB in Japan (Betanis), the United States (Myrbetriq), and Europe (Betmiga), and its properties and clinical effects have been extensively reviewed (Sacco and Bientinesi, 2012; Andersson et al, 2013b; Bridgeman et al, 2013; Chapple et al, 2014b). There are proof-of-concept studies for other β_3 -AR selective agonists such as solabegron and ritobegron (Igawa and Michel, 2013). However, the development of ritobegron has been ceased because it failed to reach the primary efficacy end point in phase III studies. Other agents—for example, TRK-380 (Kanie et al, 2012)—are in preclinical development for the treatment of the OAB syndrome.

Mirabegron

Pharmacokinetics. Mirabegron is rapidly absorbed after oral administration. It circulates in the plasma as the unchanged form, its glucuronic acid conjugates and other metabolites, the metabolites being inactive (Takusagawa et al, 2012b). Of the administered dose, 55% is excreted in urine, mainly as the unchanged form, and 34% is recovered in feces, almost entirely as the unchanged form. Mirabegron is highly lipophilic and is metabolized in the liver via multiple pathways, mainly by cytochrome P450 3A4 and 2D6 (CYP3A4, CYP2D6) (Takusagawa et al, 2012a, 2012c). It may therefore be subject to clinically relevant drug-drug interactions and should be used with caution in patients who are taking ketoconazole or other potent CYP3A4 inhibitors.

T_{max} in both extensive and poor metabolizers was about 2 hours, and the terminal elimination half-life ($t_{1/2}$) approximately 23 to 25 hours (Eltink et al, 2012; Krauwinkel et al, 2012).

Efficacy. Several phase II RCTs have shown that in OAB patients mirabegron consistently improved mean number of micturitions in 24 hours and number of continence episodes in 24 hours (Chapple et al, 2013a, 2013b, 2013c). Mirabegron was further evaluated in three pivotal phase III, 12-week RCTs in patients with OAB symptoms of UII, urgency, and urinary frequency (Herschorn et al, 2013; Khullar et al, 2013; Nitti et al, 2013a). These trials had basically similar design. Entry criteria required that patients had symptoms of OAB for at least 3 months' duration, at least eight micturitions per day, and at least three episodes of urgency with or without incontinence over a 3-day period. The majority of patients were Caucasian (94%) and female (72%) with a mean age of 59 years (range 18 to 95 years).

In the study by Nitti and colleagues (2013a), 1329 patients were randomized to receive placebo or mirabegron 50 or 100 mg once daily for 12 weeks. Coprimary end points were change from baseline to final visit (study end) in the mean number of incontinence episodes per 24 hours and micturitions per 24 hours. At the final visit, mirabegron 50 and 100 mg showed statistically significant improvements in the coprimary efficacy end points and MVV per micturition compared with placebo.

Khullar and colleagues (2013) performed a similarly designed study enrolling 1978 patients. The study included a fourth arm in which tolterodine sustained release (SR) 4 mg was used as a comparator. As in the study of Nitti and colleagues (2013a), it was found that mirabegron caused a statistically significant improvement from baseline compared with placebo in the number of urgency incontinence episodes and number of micturitions per 24 hours. Mirabegron 50 and 100 mg were statistically superior to placebo, whereas tolterodine was not, in these two key OAB symptoms, but the study was not powered for head-to-head evaluation.

In a third phase III study in which Herschorn and colleagues (2013) evaluated the effects of 25 and 50 mg of mirabegron, both doses were associated with significant improvements in efficacy measures of incontinence episodes and micturition frequency.

Nitti and colleagues (2013c) reported on the effects of mirabegron on maximum urinary flow rate and detrusor pressure at maximum flow rate in a urodynamic safety study on male patients with BOO and LUTS. Two hundred men with OAB symptoms and

a BOO Index score above 20 were randomized to receive placebo, mirabegron 50 mg, or mirabegron 100 mg once daily for 12 weeks. Mirabegron did not adversely affect flow rate, detrusor pressure at maximum flow rate, or bladder contractile index and was well tolerated.

Chapple and colleagues (2013c) compared the safety and efficacy of long-term administration of mirabegron 50 and 100 mg and tolterodine in a 12-month three-armed, parallel group study (no placebo arm). A total of 812 (50 mg) and 820 (100 mg) patients were randomized to receive mirabegron, and 812 patients received tolterodine ER 4 mg. The primary variable was incidence and severity of treatment-emergent adverse, and secondary variables were changes from baseline at months 1, 3, 6, 9, and 12 in key OAB symptoms. Both mirabegron and tolterodine improved key OAB symptoms from the first measured time point of 4 weeks, and efficacy was maintained throughout the 12-month treatment period.

Tolerability and Adverse Effects. In a proof-of-concept study of mirabegron 100 and 150 mg bid (Chapple et al, 2013a), adverse events were experienced by 45.2% of the patients—the incidence was similar among those treated with placebo (43.2%) and mirabegron (43.8% to 47.9%). The most commonly reported adverse events considered to be treatment related were gastrointestinal disorders, including constipation, dry mouth, dyspepsia, and nausea. There was no patient-reported acute retention. No significant difference in ECG parameters between the groups was demonstrated. However, a small but significant increase in mean pulse rate was observed after mirabegron 100 mg and 150 mg (1.6 and 4.1 beats/min, respectively), although this was not associated with an increase in cardiovascular adverse events in this study. The overall discontinuation rate resulting from adverse events was 3.2% (placebo 3.0% vs. mirabegron 2.4% to 5.3%).

In the study of Khullar and colleagues (2013), the incidence of adverse effects was similar across the placebo and mirabegron 50- and 100-mg groups (50.1%, 51.6%, and 46.9%, respectively). The most common ($\geq 3\%$) adverse effects in any treatment group were hypertension (6.6%, 6.1%, and 4.9%, respectively), urinary tract infection (1.8%, 2.7%, and 3.7%), headache (2.0%, 3.2%, and 3.0%), and nasopharyngitis (2.9%, 3.4%, and 2.5%). The incidence of dry mouth was similar in the placebo and mirabegron groups (2.6% vs. 2.8%) and lower than observed in patients receiving tolterodine SR (10.1%). The incidence of constipation was similar in all treatment groups (placebo, 1.4%; mirabegron, 1.6%), including tolterodine (2.0%).

In the 12-month safety and efficacy study of mirabegron referred to previously (Chapple et al, 2013c), the incidence and severity of treatment-emergent and serious adverse effects (primary outcome parameters) were similar across the mirabegron 50-mg (59.7%), mirabegron 100-mg (61.3%), and tolterodine SR 4-mg (62.6%) groups. The most frequent treatment-emergent adverse effects were hypertension, constipation, and headache, which occurred at a similar incidence across all treatment groups; the incidence of dry mouth was more than threefold lower compared with the tolterodine SR 4-mg group (Chapple et al, 2013c).

One concern with the use of β_3 -AR agonists has been the possibility of negative cardiovascular effects. In healthy subjects, mirabegron (50 to 300 mg/day for 10 days) increased blood pressure in a dose-dependent manner (Mirabegron prescribing information, 2012). However, in the studies on OAB patients, the mean increase (compared with placebo) in systolic and diastolic blood pressure after therapeutic doses of mirabegron once daily was approximately 0.5 to 1 mm Hg and was reversible on discontinuation of treatment.

In a study of healthy volunteers, mirabegron increased heart rate in a dose-dependent manner. Maximum mean increases in HR from baseline for the 50-mg, 100-mg, and 200-mg dose groups compared with placebo were 6.7 beats/min, 11 beats/min, and 17 beats/min, respectively, in healthy volunteers (Mirabegron prescribing information, 2012). However, in the clinical efficacy and safety studies, the change from baseline in mean pulse rate for mirabegron 50 mg was approximately 1 beat/min and reversible on discontinuation of treatment.

The cardiac safety of mirabegron was evaluated in a thorough QT/QTc (HR-corrected QT interval) study, including supratherapeutic dose. This was a randomized, placebo- and active- controlled (moxifloxacin 400 mg) four-treatment-arm parallel crossover study (Malik et al, 2012), and the design followed the recommendations of the International Conference on Harmonisation (ICH). Equal numbers of men and women were enrolled in each treatment group, and the pharmacokinetic and pharmacodynamic analyses included 333 and 317 subjects, respectively. The effect of multiple doses of mirabegron 50 mg, 100 mg, and 200 mg once daily on QTc interval was studied, and according to ICH E14 criteria, mirabegron did not cause QTcI prolongation at the 50-mg therapeutic and 100-mg supratherapeutic doses in patients of either sex. Mirabegron prolonged QTcI interval at the 200-mg supratherapeutic dose (upper one-sided 95% CI >10 msec) in women, but not in men.

Even if the cardiovascular effects of mirabegron observed in clinical studies have been minimal and clinically not relevant, effects on HR and blood pressure need to be monitored when the drug is prescribed and patients with cardiovascular morbidities are treated.

Phosphodiesterase Inhibitors

Drugs stimulating the generation of cAMP are known to relax smooth muscles, including the detrusor (Andersson et al, 1999; Andersson and Wein, 2004). It is also well established that drugs acting through the nitric oxide (NO)/cyclic guanosine monophosphate (cGMP) system can relax the smooth muscle of the bladder outflow region (Andersson and Arner, 2004). Use of PDE inhibitors to enhance the presumed cAMP- and cGMP-mediated relaxation of LUT smooth muscles (detrusor prostate, urethra) should then be a logical approach (Andersson et al, 2007; Andersson, 2011c; Ückert et al, 2013). There are presently 11 families of PDEs, some of which preferentially hydrolyze either cAMP or cGMP (Ückert et al, 2006; Rahnama'i et al, 2013).

As a basis for PDE inhibitor treatment of LUTS, Ückert and colleagues (2006) investigated human bladder tissue, revealing mRNA for PDE types 1A, 1B, 2A, 4A, 4B, 5A, 7A, 8A, and 9A; most of these PDE types preferably inhibit the breakdown of cAMP. In vitro, human detrusor muscle responded poorly to sodium nitroprusside and to agents acting via the cGMP system (Truss et al, 2000). However, significant relaxation of human detrusor muscle, paralleled by increases in cyclic nucleotide levels, was induced by papaverine, vinpocetine (a low-affinity inhibitor of PDE type 1 [PDE1]), and forskolin (stimulating the generation of cAMP), suggesting that the cAMP pathway and PDE1 may be important in regulation of detrusor smooth muscle tone (Truss et al, 2001). Significant dose-dependent relaxations were also induced by human cAMP analogues (Truss et al, 2001). With these studies as a background, Truss and colleagues presented preliminary clinical data for vinpocetine in patients with urgency and urgency incontinence or low-compliance bladders who were not responding to standard antimuscarinic therapy (Truss et al, 2000). This initial open pilot study suggested a possible role for vinpocetine in the treatment of OAB. However, the results of a larger RCT in patients with DO showed that vinpocetine only showed statistically significant results for one parameter (Truss et al, 2001). Studies with PDE1 inhibitors other than vinpocetine (which may not be an optimal drug for elucidation of the principle) do not seem to have been performed.

PDE4 (which also preferably hydrolyzes cAMP) has been implicated in the control of bladder smooth muscle tone. PDE4 inhibitors reduced the in vitro contractile response of guinea pig (Longhurst et al, 1997) and rat (Kaiho et al, 2008) bladder strips and also suppressed rhythmic bladder contractions of the isolated guinea pig and rat bladder (Gillespie and Drake, 2004; Nishiguchi et al, 2007). Previous experiences with selective PDE4 inhibitors showed emesis to be a dose-limiting effect (Giembycz, 2005). If this side action can be avoided, PDE4 inhibition seems to be a promising approach.

Oger and coworkers showed that the PDE5 inhibitor sildenafil-induced relaxation of human detrusor smooth muscle involved cGMP-, cAMP- and K⁺ channel-dependent signaling pathways, with a minor contribution from NO (Oger et al, 2010). In combination with the α_1 -AR antagonist doxazosin, sildenafil reduced adrenergic tone of prostatic and cavernosal smooth muscle, and their combination provided a significant benefit when targeting relaxation of both tissues (Oger et al, 2008).

In vivo, several studies have indicated a role for PDE5 inhibitors in the regulation of micturition function. Systemic vardenafil reduced both nonvoiding contractions and bladder afferent nerve firing in unanesthetized, decerebrate, spinal cord-injured rats, indicating potential mechanisms by which PDE5 inhibitors improve storage symptoms in SCI patients (Behr-Roussel et al, 2010). The effect of vardenafil on OAB symptoms could be related to a cGMP-dependent RhoA/ROCK signaling inhibition, as shown in spontaneously hypertensive rats (Morelli et al, 2009a, 2009b). Using the same animal model, bladder hypoxia was significantly reduced by acute vardenafil treatment (Morelli et al, 2009b). Thus, in addition to relaxing muscular wall, PDE5 inhibition may positively affect urinary bladder blood perfusion. In the same respect, tadalafil was shown to increase prostate tissue oxygenation in spontaneously hypertensive rats, and human vesicular-deferential artery is characterized by a high expression and activity of PDE5, which was inhibited by tadalafil in vitro; these results suggest another possible mechanism through which PDE5 inhibitors exert beneficial effects on LUTS (Morelli et al, 2011).

NO has been demonstrated to be an important inhibitory neurotransmitter in the smooth muscle of the urethra, and its relaxant effect is associated with increased levels of cGMP (Andersson and Arner, 2004). However, few investigations have addressed the cAMP- and cGMP-mediated signal transduction pathways and the key enzymes of the cGMP system in the mammalian urethra. Morita and colleagues (1994) examined the effects of isoproterenol, prostaglandin E₁ (PGE₁) and PGE₂, and sodium nitroprusside on the contractile force and tissue content of cAMP and cGMP in the rabbit urethra. They concluded that both cyclic nucleotides can produce relaxation of the urethra. Werkström and colleagues (2006) characterized the distribution of PDE5, cGMP, and protein kinase PKG1 in female pig and human urethra and evaluated the effect of pharmacologic inhibition of PDE5 in isolated smooth muscle preparations. After stimulation with the NO donor, DETA NONOate, the cGMP-immunoreactivity in urethral and vascular smooth muscles increased. There was a wide distribution of cGMP- and vimentin-positive interstitial cells between pig urethral smooth muscle bundles. PDE5 immunoreactivity could be demonstrated within the urethral and vascular smooth muscle cells, but also in vascular endothelial cells that expressed cGMP immunoreactivity. Nerve-induced relaxations of urethral preparations were enhanced at low concentrations of sildenafil, vardenafil, and tadalafil, whereas there were direct smooth muscle relaxant actions of the PDE5 inhibitors at high concentrations. Fibbi and colleagues (2009) confirmed that the highest expression and biologic activity of PDE5 was found in the bladder. However, consistent PDE5 expression and activity were also found in prostatic urethra. In contrast, the prostate gland showed the lowest PDE5 abundance, and cultures derived from this tissue were less sensitive to vardenafil. Using a different animal model associated with C-fiber afferent activation, it was shown that the NO/cGMP signaling pathway is involved in the regulation of the micturition reflex, with an action that seems more predominant on the sensory rather than on the motor component of the micturition reflex (Caremél et al, 2010).

The observation that patients treated for erectile dysfunction (ED) with PDE5 inhibitors had an improvement of their LUTS has sparked a new interest in using these drugs also for treatment of LUTS and OAB. After the report in an open study that treatment with sildenafil appeared to improve urinary symptom scores in men with ED and LUTS (Sairam et al, 2002), this observation has been confirmed in several well-designed and well-conducted RCTs.

To date, several RCTs have been published comparing the effect of PDE5 inhibitors alone with placebo, and the combination of

α_1 -AR antagonists and PDE5 inhibitors versus α_1 -AR antagonists alone (Kaplan et al, 2007; McVary et al, 2007a, 2007b; Bechara et al, 2008; Roehrborn et al, 2008b; Stief et al, 2008; Liguori et al, 2009; Porst et al, 2009; Tamimi et al, 2010; Tuncel et al, 2010; Porst et al, 2011; Gacci et al, 2012). In these studies, different PDE5 inhibitors and different doses were administered.

PDE5 inhibitors significantly improve IPSS and International Index of Erectile Function (IIEF) scores, but not Qmax, when compared with placebo. According to a recent meta-analysis by Gacci and coworkers (2012), differences in IPSS score were significantly lower in older and obese patients. The combination of PDE5 inhibitors and α -blockers led to significant improvements of the IPSS and IIEF scores as well as Qmax when compared with the use of α -blockers alone. Dmochowski showed that tadalafil once daily for LUTS had no significant effect on bladder function as measured by detrusor pressure at maximum urinary flow rate or maximum detrusor pressure and BOO Index score while improving IPSS (Dmochowski et al, 2010b). PDE5 inhibitors were shown to be generally safe and well tolerated.

The mechanism behind the beneficial effect of the PDE inhibitors on LUTS and OAB and their site(s) of action largely remain to be elucidated (Andersson et al, 2011b; Giuliano et al, 2013). If the site of action were the smooth muscles of the outflow region (and the effect relaxation), an increase in flow rate should be expected. No such effect was found in urodynamic studies (Dmochowski et al, 2010b, 2013). However, there are several other structures in the LUT that may be involved, including those in the urothelial signaling pathway (urothelium, interstitial cells, and suburothelial afferent nerves). In general, it is believed that major mechanisms contributing to LUTS include reduced NO/cGMP signaling pathway, increased RhoA-kinase pathway activity, autonomic overactivity, increased bladder afferent activity, and pelvic ischemia (Andersson et al, 2011b). Nomiya and colleagues (2013) found in a rat model of chronic bladder ischemia that tadalafil had a marked protective effect, preventing both functional and morphologic bladder changes induced by progressive ischemia. This is in line with the proposal by Cellek and colleagues (2013) linking the effectiveness of PDE5 inhibitors on BPH and LUTS (and ED) to microvascular dysfunction within the pelvic organs. They suggested that a combination of endothelial and neural dysfunction may lead to a vicious cycle of hypoxia, vasoconstriction, altered smooth muscle contractility, and degeneration of autonomic neurons and ganglia.

It has to be mentioned that as of the time of this writing, only tadalafil has been approved for the treatment of LUTS caused by benign prostatic obstruction (BPO); long-term experience with PDE5 inhibitors in patients with LUTS is still lacking (Oelke et al, 2014). In addition, insufficient information is available on the combination of PDE5 inhibitors with other LUTS medications such as 5 α -reductase inhibitors.

Antidepressants

Some clinicians believe that tricyclic antidepressants, particularly imipramine (Tofranil, others), are useful agents for facilitating urine storage, both by decreasing bladder contractility and by increasing outlet resistance (Wein, 1995a; 1995b). These agents have been the subject of a voluminous amount of highly sophisticated pharmacologic investigation to determine the mechanisms of action responsible for their varied effects (Maggi et al, 1989a; Richelson, 1994; Baldessarini, 2006). Most data have been accumulated as a result of trying to explain the antidepressant properties of these agents and are thus primarily from CNS tissue. The results, conclusions, and speculations inferred from the data are extremely interesting, but it should be emphasized that it is essentially unknown whether they apply to or have relevance for the LUT.

Tricyclic antidepressants possess varying degrees of at least three major pharmacologic actions: (1) They have central and peripheral antimuscarinic effects at some, but not all, sites; (2) they block the active transport system in the presynaptic nerve ending that is responsible for the reuptake of the released amine

neurotransmitters norepinephrine and serotonin; and (3) they are sedatives, an action that occurs presumably on a central basis but is perhaps related to antihistaminic properties (at H_1 receptors, although they also antagonize H_2 receptors to some extent). There is also evidence that they desensitize at least some α_2 - and some β -ARs. Paradoxically, they also have been shown to block some α -ARs and 5-HT₁ receptors.

Several antidepressants have been reported to have beneficial effects in patients with DO (Martin and Schiff, 1984; Lose et al, 1989). However, the use of antidepressants was shown to be an independent risk factor for LUTS suggestive of BPH in a community-based population of healthy aging men (Kok et al, 2009).

Imipramine. Imipramine is the only drug that has been widely used clinically to treat storage symptoms. Imipramine has complex pharmacologic effects, including marked systemic antimuscarinic actions (Baldessarini, 2006) and blockade of the reuptake of serotonin and NA (Maggi et al, 1989b), but its mode of action in DO has not been established (Hunsballe and Djurhuus, 2001). Even if it is considered that imipramine is a useful drug in the treatment of DO, no good-quality RCTs that can document this have been retrieved. It has been known for a long time that imipramine can have favorable effects in the treatment of nocturnal enuresis in children, with a success rate of 10% to 70% in controlled trials (Hunsballe and Djurhuus, 2001; Glazener et al, 2003). It is well established that therapeutic doses of tricyclic antidepressants, including imipramine, may cause serious toxic effects on the cardiovascular system (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine (Bigger et al, 1977; Giardina et al, 1979). Children seem particularly sensitive to the cardiotoxic action of tricyclic antidepressants (Baldessarini, 2006). The risks and benefits of imipramine in the treatment of voiding disorders do not seem to have been assessed. Very few studies have been performed during the last decade (Hunsballe and Djurhuus, 2001; Natalin et al, 2009). No good-quality RCTs have documented that the drug is effective in the treatment of DO. However, a beneficial effect has been documented in the treatment of nocturnal enuresis.

A prospective (no controls) study of the impact of the “three-drug therapy” (antimuscarinic, α -blocker, and tricyclic antidepressants) on refractory DO showed a significant increase in bladder capacity and decreases in urgency, urge incontinence, and frequency. Objective urodynamic data as well as symptom score improved significantly with triple therapy (Natalin et al, 2009).

Doxepin. Doxepin is another tricyclic antidepressant that was found to be more potent, using in vitro rabbit bladder strips, than other tricyclic compounds with respect to antimuscarinic and muscletropic relaxant activity (Levin and Wein, 1984). Lose and colleagues (1989), in a randomized, double-blind crossover study of women with involuntary bladder contractions and frequency, urgency, or urgency incontinence, found that this agent caused a significant decrease in urine loss (pad-weighing test), and in the cystometric parameters of first sensation and maximal bladder capacity. The dose of doxepin used was either a single 50-mg bedtime dose or this dose plus an additional 25 mg in the morning. The number of daytime incontinence episodes decreased in both doxepin and placebo groups, and the difference was not statistically significant. Doxepin treatment was preferred by 14 patients, whereas 2 preferred placebo. Three patients had no preference. Of the 14 patients who stated a preference for doxepin, 12 claimed that they became continent during treatment, whereas 2 claimed improvement; the 2 patients who preferred placebo claimed improvement. The Agency for Health Care Policy and Research (AHCPR) guidelines combine results for imipramine and doxepin, citing only three RCTs, with an unknown percent of female patients. Percent cures (all figures refer to percent drug effect minus percent effect on placebo) are listed as 31%, percent reduction in urgency incontinence as 20% to 77%, and percent side effects as 0% to 70% (AHCPR, 1992).

Milnacipran Hydrochloride and Paroxetine Hydrochloride. Milnacipran hydrochloride, a serotonin-norepinephrine reuptake inhibitor

(SNRI), and paroxetine hydrochloride, a selective serotonin reuptake inhibitor (SSRI), were analyzed in a prospective open trial in neurogenic OAB patients (Sakakibara et al, 2008). Milnacipran reduced daytime urinary frequency, improved the QoL index score, and increased bladder capacity as shown in urodynamic studies. No such changes were noted in the other categories of the LUTS questionnaire or urodynamic studies, or in the paroxetine group.

Duloxetine. Duloxetine is an NA-serotonin reuptake inhibitor that has been shown to significantly increase sphincteric muscle activity during the filling and storage phase of micturition in the cat acetic acid model of irritated bladder function (Thor and Katofiasc, 1995; Katofiasc et al, 2002). Bladder capacity was also increased in this model, with both effects mediated centrally through both motor efferent and sensory afferent modulation (Fraser et al, 2003). The effects of duloxetine were studied in a placebo-controlled study of 306 women (aged 21 to 84 years) with OAB, randomly treated with placebo (153) or duloxetine (80 mg/day for 4 weeks, which was increased to 120 mg/day for 8 weeks) (Steers et al, 2007). The primary efficacy analysis compared the treatment effects on mean change from baseline to end point in the mean number of voiding episodes per 24 hours. Patients randomized to duloxetine had significant improvements over those randomized to placebo for decreases in voiding and incontinence episodes (−1.81 vs. −0.62), for increases in the daytime voiding intervals (29 vs. 7 minutes), and for improvements in Incontinence Quality of Life (I-QoL) scores at both doses of duloxetine. Urodynamic studies showed no significant increases in maximum cystometric capacity or in the volume threshold for DO. The most common treatment-emergent adverse events with duloxetine (nausea 31% [placebo 4.6%], dry mouth 16% [placebo 1.3%], dizziness 14% [placebo 0.7%], constipation 14% [placebo 3.3%], insomnia 13% [placebo 1.3%], and fatigue 11% [placebo 2.0%]) were the same as those reported by women with stress urinary incontinence (SUI) (see later) and were significantly more common with duloxetine than placebo. Also, in women with mixed incontinence, improvement of the OAB component has been demonstrated (Bent et al, 2008; Schagen van Leeuwen et al, 2008). For assessment, see Table 79-3.

Side Effects and Cardiovascular Risks. With the typically larger doses used for antidepressant effects, the most frequent side effects of the tricyclic antidepressants are those attributable to their systemic antimuscarinic activity (Richelson, 1994; Baldessarini, 2006). Allergic phenomena, including rash, hepatic dysfunction, obstructive jaundice, and agranulocytosis may also occur, but rarely. CNS side effects may include weakness, fatigue, Parkinsonian effect, a fine tremor noted most in the upper extremities, a manic or schizophrenic picture, and sedation, probably from an antihistaminic effect. Postural hypotension may also be seen, presumably on the basis of selective blockade (a paradoxical effect) of α_1 -ARs in some vascular smooth muscle. Tricyclic antidepressants can also cause excess sweating of obscure cause and a delay of orgasm or orgasmic impotence, the cause of which is likewise unclear. They can also produce arrhythmias and interact in deleterious ways with other drugs, so caution must be observed in their use in patients with cardiac disease (Baldessarini, 2006). Whether cardiotoxicity will prove to be a legitimate concern in patients receiving the smaller doses (than for treatment of depression) for LUT dysfunction remains to be seen but is a potential matter of concern. Consultation with a patient’s internist or cardiologist is always helpful before instituting such therapy in questionable situations. It is well established that therapeutic doses of tricyclic antidepressants, including imipramine, may cause serious toxic effects on the cardiovascular system (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine (Bigger et al, 1977; Giardina et al, 1979). Children seem particularly sensitive to the cardiotoxic action of tricyclic antidepressants (Baldessarini, 2006).

With respect to the potential cardiovascular risks of antidepressant medication, two additional points need to be made. First of all, it may be depression itself that is associated with an increased

risk of myocardial infarction, cardiovascular disease, and all-cause mortality (see references in [Cohen et al, 2000](#)). Although treatments for depression, including antidepressive medications, are certainly a potential factor underlying this association, the separation from disease association and treatment association is difficult at best. The second point relates to whether there is a difference in this regard between the use of tricyclic antidepressants and SSRIs. Data presented by [Cohen and coworkers \(2000\)](#) suggest that with respect to long-term adverse cardiovascular outcome, there is an association between the use of tricyclic antidepressants but not SSRIs, a conclusion that differs from earlier data, indicating no significant differences in the safety or efficacy of these two groups of agents (AHCPR report, cited by [Cohen et al, 2000](#)). As a closing statement on this subject, it should be noted that data in the literature refer to therapeutic doses of these medications for depression and not the smaller (in comparison) doses of imipramine used for the treatment of voiding dysfunction.

The use of imipramine is contraindicated in patients receiving monoamine oxidase inhibitors, because severe CNS toxicity can be precipitated, including hyperpyrexia, seizures, and coma. Some potential side effects of the antidepressants may be especially significant for the elderly, specifically weakness, fatigue, and postural hypotension. Psychotropic drugs in general have been shown to increase the risk of falls and hip fractures in the elderly ([Liu et al, 1998](#)). If imipramine or any of the tricyclic antidepressants is to be prescribed for the treatment of voiding dysfunction, the patient should be thoroughly informed of the fact that this is not the usual indication for this drug and that potential side effects exist. Reports of significant side effects (severe abdominal distress, nausea, vomiting, headache, lethargy, and irritability) after abrupt cessation of high doses of imipramine in children would suggest that the drug should be discontinued gradually, especially in patients receiving high doses.

Cyclooxygenase Inhibitors

Human bladder mucosa has the ability to synthesize eicosanoids ([Jeremy et al, 1987](#)), and these agents can be liberated from bladder muscle and mucosa in response to different types of trauma ([Downie and Karmazyn, 1984](#); [Leslie et al, 1984](#)). Even if prostaglandins cause contraction of human detrusor ([Andersson, 1993](#)), it is still unclear whether prostaglandins contribute to the pathogenesis of DO. More important than direct effects on the bladder muscle may be sensitization of sensory afferent nerves, increasing the afferent input produced by a given degree of bladder filling. Involuntary bladder contractions can then be triggered at a small bladder volume. If this is an important mechanism, treatment with prostaglandin synthesis inhibitors could be expected to be effective. However, clinical evidence for this is scarce.

[Cardozo and colleagues \(1980\)](#) performed a double-blind controlled study of 30 women with DO using the prostaglandin synthesis inhibitor flurbiprofen at a dose of 50 mg three times daily. The drug was shown to have favorable effects, although it did not completely abolish DO. There was a high incidence of side effects (43%) including nausea, vomiting, headache, and gastrointestinal symptoms. [Palmer \(1983\)](#) studied the effects of flurbiprofen 50 mg \times 4 versus placebo in a double-blind crossover trial in 37 patients with IDO (27% of the patients did not complete the trial). Active treatment significantly increased maximum contractile pressure, decreased the number of voids, and decreased the number of urgent voids compared with baseline. Indomethacin 50 to 100 mg daily was reported to give symptomatic relief in patients with DO compared with bromocriptine in a randomized, single-blind crossover study ([Cardozo and Stanton, 1980](#)). The incidence of side effects was high, occurring in 19 of 32 patients. However, no patient had to stop treatment because of side effects.

The few controlled clinical trials on the effects of prostaglandin synthesis inhibitors in the treatment of DO, and the limited number of drugs tested, makes it difficult to evaluate their therapeutic value. No new RCTs on the effects of cyclooxygenase

(COX) inhibitors in OAB and DO patients seem to have been published during the last decade.

Although these early clinical studies with nonselective COX inhibitors showed some promise in the treatment of these disorders, the drugs were not further developed for this indication, mainly because of side effects. The interest in the use of selective COX-2 inhibitors was hampered by concerns about long-term cardiovascular toxicity with these drugs.

KEY POINTS: DRUGS FOR OVERACTIVE BLADDER

- Theoretically, calcium antagonists and potassium channel openers would be attractive methods to inhibit DO and regulate detrusor smooth muscle tone. However, there is no current clinical evidence to support the use of either class of drug in the treatment of bladder dysfunction. The use of α -adrenergic antagonists to treat storage symptoms in men, as distinct from their effect on voiding symptoms, is somewhat unclear. Some studies suggest no effect of commonly used agents, whereas other studies suggest that selective blockade of α_{1A} -ARs is clinically effective, albeit associated with a high incidence of ejaculatory dysfunction. In women, treatment of OAB filling and storage symptoms with α_{1A} antagonists seems ineffective.
- The most recent drug approved for the treatment of OAB is a β_3 -AR agonist, mirabegron, which acts both to relax and maintain low detrusor tone during filling and also to inhibit activity in sensory afferents in an animal model. In such a model, these drugs increase bladder capacity but do not change voiding pressure or voiding volume. Clinically, mirabegron, the only such agent currently available, improves OAB symptoms without affecting emptying parameters. The side effect profile is quite different from that of the antimuscarinic agents, and some concern exists regarding negative cardiovascular effects (blood pressure and HR); in clinical studies these have been minimal and clinically not relevant, but it has been recommended that these be monitored during treatment.
- There are logical theoretic mechanisms whereby PDE inhibitors should enhance the relaxation of LUT smooth muscle. PDE5 inhibitors have been shown to have beneficial effects on LUTS, including those of OAB, although their site(s) and mechanism(s) remains to be established.
- Although there are theoretic mechanisms by which tricyclic antidepressants, particularly imipramine, should facilitate storage, both by decreasing bladder contractility and increasing outlet resistance, there are no good-quality randomized controlled trials to adequately test this hypothesis. Duloxetine, primarily a noradrenalin-serotonin reuptake inhibitor, has been shown to increase some significant storage symptoms, but trials directed specifically toward this effect are lacking. Although there are theoretic mechanisms by which prostaglandin synthesis inhibitors could affect filling and storage symptoms, clinical evidence for this is scarce.

Other Drugs

Dimethyl Sulfoxide. Dimethyl sulfoxide (DMSO) is a relatively simple, naturally occurring organic compound that has been used as an industrial solvent for many years. It has multiple pharmacologic actions (membrane penetrant, anti-inflammatory, local analgesic, bacteriostatic, diuretic, cholinesterase inhibitor, collagen solvent, vasodilator) and has been used for the treatment of arthritis and other musculoskeletal disorders, usually in a 70% solution. The formulation for human intravesical use is a 50% solution. [Sant \(1987\)](#) has summarized the pharmacology and clinical use of DMSO and has tabulated "good to excellent" results in 50% to 90% of collected series of patients treated with intravesical instillation for interstitial cystitis. However, DMSO has not been shown to be

useful in the treatment of NDO or IDO or in any patients with urgency or frequency but without interstitial cystitis. The subject of interstitial cystitis and its treatment is considered in Chapter 14. **Baclofen.** γ -Aminobutyric acid (GABA) is a ubiquitous inhibitory neurotransmitter in the CNS that can inhibit the micturition reflex at several points along its central pathway (de Groat, 1997; Pehrson and Andersson, 2002). Experimental data suggest the GABAergic system as an interesting target for bladder dysfunction therapy. Baclofen intrathecally attenuated oxyhemoglobin-induced DO, suggesting that the inhibitory actions of GABA-B-receptor agonists in the spinal cord may be useful for controlling micturition disorders caused by C-fiber activation in the urothelium and/or suburothelium (Pehrson and Andersson, 2002). In spinal-intact rats, intrathecal application of bicuculline induced detrusor-sphincter dyssynergia (DSD)-like changes, whereas intrathecal application of baclofen induced urethral relaxation during isovolumetric bladder contractions (Miyazato et al, 2008). Miyazato and colleagues (2008) found signs of hypofunction of the GABAergic system after SCI (glutamate decarboxylase 67 mRNA levels in the spinal cord and dorsal root ganglia were decreased), and showed that activation of GABA-A and GABA-B receptors in the spinal cord inhibited DO as evidenced by a reduction in nonvoiding contractions. GABA-B-receptor activation preferentially reduced DO before inhibiting voiding contractions, whereas GABA-A-receptor activation inhibited DO and voiding contraction at the same concentration.

As a GABA agonist on GABA-B receptors, baclofen was used orally in IDO patients. However, its efficacy was poor, eventually dictated by the fact that baclofen does not cross the blood-brain barrier (Taylor and Bates, 1979). Baclofen is one of the most effective drugs for the treatment of spasticity after SCI, traumatic or hypoxic brain injury, and cerebral palsy (Ochs, 1993), and intrathecal baclofen was shown to be useful in some patients with spasticity and bladder dysfunction (Bushman et al, 1993). Baldo and colleagues (2000) found a rapid (24 hours) and persistent increment in the volume to first detrusor contraction (FDC) and of the maximal cystometric capacity, whereas maximal detrusor pressure decreased. At 10 days the volume to FDC had increased from 143 mL to 486 mL. In selected patients with spasticity and bladder dysfunction, intrathecal baclofen seems to be an effective therapy.

Combinations

α_{1A} -Adrenergic-Receptor Antagonists with Antimuscarinics. Traditionally, male LUTS were thought to result from BPO secondary to BPE. However, male LUTS may arise from prostatic pathology, bladder dysfunction, or both. Thus, diagnosis and appropriate treatment of men with OAB symptoms are complex and difficult. α_1 -AR antagonists remain the most widely used pharmacologic agents for relief of bladder outflow resistance, as they relax prostatic and urethral smooth muscle tone, the dynamic component of BPO (Andersson and Gratzke, 2007; Lepor et al, 2012). In contrast, antimuscarinics, which function by competitively blocking the muscarinic receptors, are the first-line pharmacologic treatment for OAB (Andersson et al, 2009). Given the prevalence of combined voiding and OAB symptoms as well as the finding that the QoL of these patients is affected primarily by the symptoms of OAB, it might be logical for this category of patients to be given antimuscarinic drugs (Ruggieri et al, 2005).

A variety of such combinations have been evaluated. Several randomized, controlled trials demonstrated that the combination treatment of antimuscarinic drugs and α_1 -AR antagonists was more effective at reducing male LUTS than α_1 -AR antagonists alone in men with OAB and coexisting BPO (Saito et al, 1999; Athanasopoulos et al, 2003; Lee et al, 2004, 2005; Kaplan et al, 2006, 2007). Therapeutic benefit of combining an antimuscarinic agent (propiverine) with an α_1 -AR antagonist (tamsulosin), as compared with an α_1 -AR antagonist alone, was reported by Saito and colleagues (Saito et al, 1999). The rates of improvement in daytime frequency, incontinence, and urgency were greater in the combination group than the α_1 -AR antagonist-alone group. The PVR was

unchanged in both groups, and there was only one case (1.5%) of AUR with the combined treatment.

Subsequently, Lee and colleagues (2005) compared the efficacy and safety of combination therapy with propiverine and doxazosin in 211 men with urodynamically confirmed BOO and OAB symptoms for 8 weeks. Compared with the doxazosin arm, the patients in the combination therapy group showed greater improvement in urinary frequency, average micturition volume, and storage and urgency scores of IPSS. Patient satisfaction was significantly higher in the combination group. There was also a significant increase in PVR (+20.7 mL) in the combination group, but no case of urinary retention was reported.

A large-scale, multicenter, randomized, double-blind, placebo-controlled trial (the TIMES study) demonstrated the efficacy and safety of tolterodine ER alone, tamsulosin alone, and the combination of both in 879 men with OAB and BPO (Kaplan et al, 2006). In the primary efficacy analysis, 172 men (80%) receiving tolterodine ER plus tamsulosin reported treatment benefits by week 12 ($P < .001$ vs. placebo; $P = .001$ vs. tolterodine ER; $P = .03$ vs. tamsulosin). In the secondary efficacy analysis, patients receiving tolterodine ER plus tamsulosin compared with placebo experienced small but significant reductions in urgency incontinence, urgency episodes, daytime frequency, and nocturia. However, there were no significant differences between tamsulosin monotherapy and placebo for any diary variables at week 12. Patients receiving tolterodine ER plus tamsulosin demonstrated significant improvements in total IPSS (−8.02 vs. placebo −6.19, $P = .003$) and QoL (−1.61 vs. −1.17, $P = .003$). Although there were significant improvements in the total IPSS among patients who received tamsulosin alone, the differences in total IPSS among patients who received tolterodine ER versus placebo were not significant. The combination of antimuscarinics and α_1 -AR antagonists may be the most effective therapy in men with OAB symptoms in the presence of BPO.

A subanalysis (Rovner et al, 2008a) of data from the TIMES study focused on the urgency perception scale and concluded that the group of 217 men who received tolterodine plus tamsulosin showed significantly improved urgency variables and patient-reported outcomes. Moreover, this group of patients reported increased satisfaction with the treatment as well as willingness to continue the treatment. Another subanalysis (Kaplan et al, 2008a) of data from the TIMES study examined the effects of the drugs on urinary symptoms as assessed by the IPSS. Based on this subanalysis, the authors concluded that tolterodine ER plus tamsulosin was significantly more effective than placebo in treating storage LUTS, including OAB symptoms. However, these results should be considered with caution because they were derived from post hoc analysis of the TIMES data.

Maruyama and colleagues (2006) reported different results in their prospective, randomized, controlled study in which naftopidil (25 to 75 mg/day), an α_{1D} -AR antagonist, alone or in combination with propiverine hydrochloride (10 to 20 mg/day) or oxybutynin hydrochloride (2 to 6 mg/day), was administered for 12 weeks to 101 BPH patients. In the study, the IPSS and QoL index score improved significantly in both groups, with no marked differences between groups. Qmax and PVR tended to improve in both groups, again with no differences between groups. However, median post-therapeutic PVR was significantly larger in the combination group (45.0 mL) than in the monotherapy group (13.5 mL, $P = .021$). There were significantly more patients with increased residual urine volume relative to unchanged residuals in the combination therapy (22.9%) group versus the monotherapy group (5.0%, $P = .038$). The authors of this study concluded that combination therapy with a low-dose antimuscarinic agent was not more effective than monotherapy. Moreover, although they did not encounter any cases of urinary retention, the percentage of patients with increased residual urine volume was significantly greater in the combination therapy group than in the monotherapy group.

The results of another study using low-dose antimuscarinic therapy was published by Kang and colleagues (2009). They evaluated the efficacy and safety of combined treatment with tamsulosin

0.2 mg and propiverine hydrochloride 10 mg compared with tamsulosin monotherapy. After 3 months, both groups showed significant improvements in IPSS, QoL, voided volume, Qmax, and PVR, but only the QoL index was significantly different between groups in favor of the combination group. No cases of AUR were recorded in this low-dose study.

Medical therapy to reduce DO in a neurogenic bladder has focused on antimuscarinic therapy, which increases bladder capacity, decreases bladder filling pressure, and improves compliance (Goessl et al, 1998; Stöhrer et al, 2009). Although use of antimuscarinics combined with clean intermittent catheterization (CIC) is the most commonly recommended medical therapy for neurogenic bladder, the results are sometimes unsatisfactory, and many patients continue to have poor bladder compliance and remain incontinent (Razdan et al, 2003). McGuire and Savastano (1985) reported that α_1 -AR antagonists decreased bladder pressure with filling and increased capacity, and that the addition of an antimuscarinic enhanced these effects, indicating that α_1 -AR antagonists and the antimuscarinic had a synergistic effect on detrusor tone in the decentralized bladder. This finding led to the widespread use of α_1 -AR antagonists in the treatment of neurogenic bladder (Chancellor et al, 1994; Swierzewski et al, 1994; Abrams et al, 2003). Swierzewski treated 12 patients with SCI who had poor bladder compliance, despite therapy with CIC and an antimuscarinic, with 5 mg of terazosin for bladder management (Swierzewski et al, 1994). After 4 weeks, compliance increased by 73%, bladder pressure decreased by 36 cm H₂O, and capacity increased by 157 mL. These results support the assumption that α_1 -AR antagonists and antimuscarinics may have an additional synergistic effect on the bladder in the neurogenic population.

In a retrospective chart review, combination therapy with an antimuscarinic agent, an α_1 -AR antagonist, and imipramine produced superior results to those obtained using a single agent in patients with neurogenic bladder dysfunction (Cameron et al, 2009). These patients showed significant improvement in clinical parameters and compliance and decreased bladder pressures at capacity. It has been shown that in the decentralized human detrusor, there may be an increase in α -AR sites and a switch to α -AR-mediated contractile function from the typical β -AR-mediated relaxation function during bladder filling (Sundin et al, 1977). Imipramine is a systemic muscarinic-receptor antagonist and a direct smooth muscle inhibitor that also blocks the reuptake of serotonin and NA. This suggests that targeting multiple receptors may maximize the effectiveness of pharmacologic treatment of neurogenic bladder and should be considered in patients in whom treatment with antimuscarinics alone fails.

β_3 -Adrenergic-Receptor Antagonists with Antimuscarinics. β_3 -AR agonists exert their therapeutic effects through stimulation of adenyl cyclase and activation of potassium K⁺ channels. The former leads to an increase in cAMP and the latter to hyperpolarization, both of which result in relaxation. The beneficial effects of modulation of these pathways are inhibition of spontaneous activity, increased bladder compliance (decreased bladder tone during filling), greater distention needed to activate the micturition reflex (increased bladder capacity), and decreased afferent activity, with no effect on voiding contraction (no risk for urinary retention).

These mechanisms are distinct from those of antimuscarinic therapies used to treat OAB. Accordingly, the combination of these two types of medications is being investigated to determine whether concomitant use can result in increased efficacy with an acceptable profile of safety and tolerability. Based on results with an animal model it was concluded that the "combination of antimuscarinics and β_3 -AR agonists can result in increased efficacy and potency and supports the hypothesis that combining these compound classes in the clinic could have beneficial effects in treating urinary bladder dysfunction" (Rekik et al, 2013). In a phase II clinical study (the Symphony study) evaluating the combination of solifenacin and mirabegron in 1307 patients with OAB (Abrams et al, 2013), the patients were randomized to receive one of six combinations—mirabegron 25 or 50 mg in combination with solifenacin 2.5, 5, or 10 mg; or monotherapy with mirabegron or

solifenacin (at each of the same doses studied in the combinations); or placebo. The study duration was 12 weeks. The primary efficacy variable was change in MVV per micturition; secondary variables included change in micturition frequency and incontinence episode frequency (IEF) per 24 hours. The investigators reported that mirabegron combination therapy with solifenacin (the latter at a dose exceeding 5 mg) demonstrated greater efficacy than solifenacin 5 mg alone on MVV and micturition frequency (Abrams et al, 2013). The enhanced efficacy with the combination was of a magnitude that is probably similar to the enhanced efficacy one might expect from up-titrating the dose of the antimuscarinic. However, the combination was not associated with the adverse effects one would expect to encounter with higher doses of antimuscarinics. In this study, all six combinations appeared to be well tolerated and there appeared to be no safety concern or significant increase in adverse effects with the combination treatment compared with either monotherapy (Abrams et al, 2013).

Combined Antimuscarinics. Although antimuscarinic agents are the first choice of treatment for patients with OAB symptoms, these drugs do not always lead to the desired effect of detrusor stability and continence, especially for patients with SCI or neurologic diseases such as multiple sclerosis or meningocele. In these patients, the goal of urologic therapy is to maintain continence and to reduce intravesical pressure. When antimuscarinic treatment fails, however, invasive procedures such as the injection of botulinum neurotoxin type A (BoNTA), intravesical application of drugs, or surgery are necessary.

A combined antimuscarinic regimen was evaluated as a noninvasive alternative by Amend and colleagues (2008) for patients who had neurogenic bladder dysfunction with incontinence, reduced bladder capacity, and increased intravesical pressure. They added secondary antimuscarinics to the existing double-dose antimuscarinics for patients who previously demonstrated unsatisfactory outcomes with double-dose antimuscarinic monotherapy. The study drugs were tolterodine, oxybutynin, and trospium. After a 4-week combined regimen, incontinence episodes decreased and reflex volume, maximal bladder capacity, and detrusor compliance increased. Side effects were comparable to those seen with normal-dose antimuscarinics. Those positive findings were speculated to be the result of (1) additive or synergistic activation of different muscarinic receptors or interactions of receptors on different parts of the bladder wall, (2) undiscovered faster metabolism of antimuscarinics requiring an increased dose of different antimuscarinic drugs, and/or (3) downregulation of subdivisions of antimuscarinic receptors under monotherapy that may lead to better susceptibility of other subdivisions when treated by the second drug. The combined regimen needs further investigation to verify its efficacy as a noninvasive alternative for patients in whom antimuscarinic monotherapy fails.

Antimuscarinics and 5 α -Reductase Inhibitors. The standard first-line medical therapy for men with moderate-to-severe LUTS is an α_1 -AR antagonist, a 5 α -reductase inhibitor, or combination therapy with both. Both α_1 -AR antagonist and 5 α -reductase inhibitors alleviate LUTS in men by reducing bladder outlet resistance. α_1 -AR antagonists decrease smooth muscle tone in the prostate and bladder neck, whereas 5 α -reductase inhibitors reduce prostate volume. As mentioned, several trials have demonstrated the efficacy and safety of combination therapy with antimuscarinics and α_1 -AR antagonist for patients with OAB and coexisting BPO. However, post hoc analyses of the TIMES study (Kaplan et al, 2006) suggested that men with smaller prostates benefit more from antimuscarinic therapy than those with larger prostates (Roehrborn et al, 2008a, 2009). Chung and colleagues (2010) conducted an open-label, fixed-dose study to assess the efficacy and safety of tolterodine ER in combination with dutasteride in men with a large prostate (≥ 30 g) and persistent OAB symptoms after α_1 -AR antagonist therapy who had been unsuccessfully treated with dutasteride alone. At the start of the study, all patients had been on dutasteride 0.5 mg daily for at least 6 months and α_1 -AR antagonist therapy had failed. All patients were given 4 mg of tolterodine ER daily for 12 weeks and had discontinued α_1 -AR antagonist therapy

before the start of the study. At 12 weeks, the frequency ($-3.2/24$ hr, $P < .02$), urgency (19.2%, $P < .03$), number of severe OAB episodes (71.4%, $P < .05$), and incidence of nighttime voiding (-0.9 , $P < .003$) were found to have decreased significantly from baseline. The IPSS decreased with dutasteride treatment (from 19.3 to 14.3) and further decreased with the addition of tolterodine to 7.1 ($P < .001$). Storage symptoms decreased from 9.8 to 4.5 ($P < .001$). Dry mouth occurred in four (7.5%) patients, constipation in one (2%), and decreased sexual function in two (3.9%). PVR increased by 4.2 mL, Qmax decreased by 0.2 mL/sec, and no patients developed retention. The authors concluded that the combination of tolterodine and dutasteride was effective, safe, and well tolerated in men with large prostates with persistent OAB symptoms and LUTS secondary to BPO.

The results of this study indicate that antimuscarinics are safe and effective in selected patients with OAB and BPO when used in combination with 5 α -reductase inhibitors. Further studies are required to verify the efficacy of antimuscarinics combined with 5 α -reductase inhibitors in these patients.

α_1 -Adrenergic-Receptor Antagonists with 5 α -Reductase Inhibitors. It has been well established that the combinations of α_1 -AR antagonists with 5 α reductase inhibitors (doxazosin finasteride in Medical Therapy of Prostatic Symptoms [MTOPS] trial; dutasteride plus tamsulosin in Combination of Avodart and Tamsulosin [CombAT] study) can improve clinical outcomes and reduce the incidence of BPH and LUTS progression measured as symptom worsening, retention, or progression to surgery (McConnell et al, 2003; Roehrborn et al, 2010).

KEY POINTS: DRUGS FOR MALE LOWER URINARY TRACT SYMPTOMS

- Because male LUTS may arise from prostatic obstruction, bladder dysfunction, or both, a logical step is to combine an α_1 -adrenergic antagonist with antimuscarinics to treat such patients. There are several trials demonstrating that this combination is more effective at reducing male LUTS than just α -blockers alone in men with OAB and BPO. In these trials the PVR was unchanged. However, there is not universal agreement because other trials do not show effects. Such usage has been recorded in patients with NDO with successful results.
- Because β_3 -adrenergic agonists and antimuscarinics have different mechanisms of action, it is attractive to speculate that a combination would be more effective than either drug used alone, especially because the adverse effect profiles are different. Such trials are ongoing.
- Also under investigation is the combination of different antimuscarinic agents in patients in whom antimuscarinic monotherapy fails.
- Antimuscarinic therapy in patients with OAB symptoms and prostatic pathology is more effective in men with smaller prostates.
- It is well established that the combination of an α -adrenergic antagonist and a 5 α -reductase inhibitor will improve clinical outcomes and reduce the incidence of symptomatic progression in patients with LUTS and BPH or BPO.

Toxins

Intravesical pharmacologic therapy for LUTS stems from the fact that circumventing systemic administration of active compounds offers two potential advantages. First, high concentrations of pharmacologic agents can be given to the bladder tissue, producing enhanced local effects. Second, drugs inappropriate for systemic administration because of off-target effects can be safely used. Attractive as it may be, intravesical pharmacologic therapy should still be considered as a second-line treatment in patients refractory

to oral therapy or who do not tolerate its systemic side effects. However, this statement is based on the assumption that intervention therapy should follow oral medication. Research aiming at defining if patient subgroups will benefit from intravesical therapy as first-line treatment is clearly necessary.

Botulinum Toxin

Mechanism of Action. Botulinum toxin (BoNT) is a neurotoxin produced by *Clostridium botulinum*. Of the seven subtypes of BoNT, subtype A (BoNTA) has the longest duration of action, making it the most relevant clinically. BoNTA is available in four different commercial forms, with the proprietary names of Botox, Dysport, Xeomin, and Prosigne. Although the toxin is the same, it is wrapped by different proteins that modify the relative potency of each brand. This was the basis for the introduction of the nonproprietary names onabotulinumtoxinA (onabotA), abobotulinumtoxinA (abobotA), and incobotulinumtoxinA (incobotA) for Botox, Dysport, and Xeomin, respectively. Prosigne is the proprietary name of a BoNTA produced in China, which currently does not have a known nonproprietary name. Although potency of each one is usually expressed in units (U), the doses are not interchangeable. Clinical dose conversion studies for the LUT do not exist. Available information indicates that onabotA is roughly three times more potent than abobotA and equivalent to incobotA. Nevertheless, these equivalences should be approached with caution.

Most of the information available about intravesical application of BoNTA derives from the use of onabotA (Botox). However, in addition to subtype A, some studies have investigated the effect of detrusor injection subtype B, rimabotulinumtoxinB (proprietary names being Miobloc or Neurobloc according to countries).

BoNT consists of a heavy and a light chain linked by a disulfide bond. In the synaptic cleft the toxin binds to synaptic vesicle protein 2 (SV2) (Dong et al, 2006) by the heavy chain before being internalized by the nerve terminal along with the recycling process of synaptic vesicles. The two chains are then cleaved and the light chain passes into the cytosol, where it cleaves the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmic membrane necessary for neurotransmitter release. Attachment proteins (SNARE [soluble N-ethylmaleimide sensitive factor attachment protein receptor]) include synaptosome-associated protein 25 kD (SNAP-25), synaptobrevin (vesicle-associated membrane protein [VAMP]), and syntaxin. BoNTA cleaves SNAP-25, rendering the SNARE complex inactive (Humeau et al, 2000; Chancellor et al, 2008a). Subtype B acts preferentially through the inactivation of VAMP (Humeau et al, 2000).

BoNTA application was extensively evaluated in striated muscle. In this tissue, paralysis occurs by prevention of ACh release from cholinergic motor nerve endings (Humeau et al, 2000). Accumulation of neurotransmitter-containing synaptic vesicles is followed by terminal axonal degeneration. Striated muscle paralysis recovers within 2 to 4 months. During this time, axons develop lateral sprouts and eventually regenerate completely (de Paiva et al, 1999).

In the human bladder, SV2 and SNAP-25 expression has been demonstrated in parasympathetic, sympathetic, and sensory fibers (Coelho et al, 2010, 2012a, 2012b). Almost all parasympathetic nerves express the two proteins (Coelho et al, 2010, 2012a). Because these nerves play a fundamental role in detrusor contraction during voiding, the blockade of ACh release is believed to play an essential role in detrusor hypocontractility or acontractility that follows BoNTA injection in the bladder. In accordance with this view, it was shown that in normal or spinal cord-injured animals, BoNTA treatment decreased the bladder contractions evoked by electrical stimulation of spinal nerves without altering intrinsic contractions (Ikeda et al, 2012). However, cholinergic axon sprouting concomitant with clinical remission could not be documented in the detrusor (Haferkamp et al, 2004).

Bladder sensory impairment is also expected to play an important role in the final effect of BoNTA bladder injection. BoNTA inhibits the spinal cord release of glutamate, substance P (SP), and calcitonin gene-related peptide (CGRP) from sensory nerves (Purkiss et al, 2000; Aoki, 2005; Meng et al, 2007) as well as the

release of neuropeptides at the peripheral extremities (Rapp et al, 2006; Lucioni et al, 2008). BoNTA has also been shown to reduce the suburothelium immunoreactivity for transient receptor potential (TRP) channel TRPV1 or P2X₃ (Apostolidis et al, 2005b). Morenilla-Palao and colleagues (2004) have shown that BoNTA impedes TRPV1 trafficking from intracellular vesicles to the neuronal membrane, a process that is also dependent on SNARE proteins. All these mechanisms may contribute to the recent observation that BoNTA reduces afferent firing from bladder afferents and antidromic release of neuropeptides (Ikeda et al, 2012). Although SV2 and SNAP-25 immunoreactivity has not been detected in urothelial cells (Coelho et al, 2010), urothelial function seems also compromised after BoNTA administration. BoNTA has been shown to inhibit ATP release from urothelium in animal models of SCI (Khera et al, 2004; Smith et al, 2008). Therefore it is not surprising that administration of BoNTA to inflamed rat bladders reduces spinal c-Fos counts at the L6 and S1 spinal cord segments (Vemulakonda et al, 2005).

Cleaved, inactive SNAP-25 appears rapidly after BoNTA injection. In the guinea pig, a robust expression of cleaved SNAP-25 could be detected already at 12 hours and maximum intensity could be detected at 24 hours with little changes afterward. In guinea pigs, cleaved SNAP-25 expression was restricted to nerve fibers. Almost all parasympathetic fibers, either preganglionic and postganglionic, were affected, whereas less than half of the sensory fibers expressed the cleaved protein (Coelho et al, 2012a, 2012b). In the human urinary bladder, cleaved SNAP-25 could be detected in NDO patients up to 11 months after BoNTA injection (Schulte-Baukloh et al, 2007). The longer duration of cleaved SNAP-25 in the detrusor smooth muscle, longer than in striated muscles, has no firm explanation at the moment. However, the longer persistence of the inactive form of SNAP-25 plus the involvement of preganglionic and postganglionic parasympathetic neurons may contribute to persistence of the BoNTA effect in the bladder.

Myofibroblasts form a syncytium through extensive coupling via the gap-junction protein connexin 43 and have close contacts with sensory nerves. These facts led to the hypothesis that myofibroblasts act as modulators of bladder behavior (Wiseman et al, 2003; Apostolidis et al, 2006). However, the expression of connexin 43 is not altered by BoNTA (Roosen et al, 2009). Hence, at the moment, firm evidence for the action of BoNTA on myofibroblasts is scant.

BoNTA may decrease the levels of neurotrophic agents in the bladder tissue. Levels of nerve growth factor (NGF) (Giannantoni et al, 2006, 2013; Liu et al, 2009) and brain-derived neurotrophic factor (BDNF) (Pinto et al, 2010) have been shown to decrease in the bladder and/or urine after BoNTA injections. Because both neurotrophins have paramount roles in growth, maintenance, and plasticity of peptidergic sensory nerves, these findings may point toward another mechanism whereby BoNTA acts on the bladder.

Clinical Use. Comprehensive reviews of the clinical use of BoNTA have been produced during the last few years, covering different aspects of this treatment (Kuo, 2005a, 2005b; Chapple and Patel, 2006; Nitti, 2006; Patel et al, 2006; Kuo, 2007; Karsenty et al, 2008; Apostolidis et al, 2009; Sahai et al, 2009; Cruz et al, 2011; Dowson et al, 2011, 2012; Duthie et al, 2011; Herschorn et al, 2011a; Mangera et al, 2011; Denys et al, 2012; Fowler et al, 2012; Andersson et al, 2013a; Tincello et al, 2014).

Efficacy. RCTs have documented the clinical effects of onabotulinumtoxinA both in NDO and IDO, wherein the drug decreases incontinence episodes, frequency, and urgency and improves QoL (Sahai et al, 2007; Dmochowski et al, 2010a; Mangera et al, 2011; Tincello et al, 2012). The drug was also shown to be effective in patients with OAB (Nitti et al, 2013b). Successful OAB treatment with BoNTA does not appear to be related to the existence of DO. No differences in outcomes were found between those with and those without baseline DO (Rovner et al, 2011; Kanagarajah et al, 2012). Nitti and colleagues (2013b) reported results of the first large (N = 557) phase III placebo-controlled trial of onabotulinumtoxinA in OAB patients. To be included, patients had three or more UI episodes in 3 days and eight or more micturitions per day. They were randomized 1:1 to receive intradetrusor injection of

onabotulinumtoxinA 100 U or placebo (saline). Coprimary end points were change from baseline in UI episodes per day and proportion of patients with a positive response on the treatment benefit scale (TBS) at week 12 after treatment. Secondary end points included other OAB symptoms and health-related QoL. OnabotulinumtoxinA significantly reduced the daily frequency of UI episodes versus placebo (−2.65 vs. −0.87; $P < .001$), and 22.9% versus 6.5% of patients became completely continent. A larger proportion of onabotulinumtoxinA-treated patients than those receiving placebo reported a positive response on the TBS (60.8% vs. 29.2%; $P < .001$). All other OAB symptoms improved versus placebo ($P \leq .05$). OnabotulinumtoxinA improved patients' health-related QoL across multiple measures ($P < .001$).

The finding that onabotulinumtoxinA 100 U was consistently effective with a twofold to fourfold improvement over placebo in all symptoms of OAB is important; an effect of this magnitude versus placebo does not seem to have been reported previously with antimuscarinics or β_3 -AR agonists.

Adverse Effects. The most frequent side effects reported after intradetrusor BoNTA injection are bladder pain and urinary infections (Del Popolo et al, 2008; Karsenty et al, 2008; Kuo et al, 2010). Hematuria may also occur, most of the times mild in nature. The most dangerous side effect, paralysis of the striated musculature caused by circulatory leakage of the toxin, has never been reported. Transient muscle weakness was, nevertheless, reported with abobotA application in several studies (Wyndaele and Van Dromme, 2002; Akbar et al, 2007; Del Popolo et al, 2008). Of 199 NDO patients followed for 8 years, 5 developed hyposthenia when injected with abobotA 1000 U (Del Popolo et al, 2008). In another study with 44 patients, 3 adults also treated with 1000 U developed muscular weakness, which subsided after 5 to 7 weeks (Akbar et al, 2007). No such cases were reported with onabotA (Karsenty et al, 2008). The reason for the lack of transient muscle weakness in BoNTA-treated patients is unclear but might be related to the larger size of its molecule, which limits diffusion into the bloodstream. Caution should be used in selecting high-risk patients for treatment, including children, patients with low pulmonary reserve, and patients with myasthenia gravis. Aminoglycosides should be avoided during BoNTA treatment because they might block motor plates and therefore enhance BoNTA effect.

The most feared complication of BoNTA application in patients with voluntary voiding is urinary retention and a transient necessity to perform CIC. It is therefore strongly recommended that in patients with spontaneous voiding BoNTA administration be preceded by a complete discussion of information regarding this risk. Caregivers should ideally teach CIC to each patient before toxin injection. In the study by Nitti and colleagues (2013a), the majority of adverse effects occurred in the first 12 weeks (15.5% with onabotA vs. 5.9% with placebo). The most frequently reported adverse effect was uncomplicated urinary tract infection with no upper urinary tract involvement. Other adverse effects were dysuria (12.2%), bacteriuria (5.0%), and urinary retention (5.4%). PVR urine volume significantly increased with onabotA versus placebo, with the highest volume at week 2 after treatment, and 8.7% of patients had an increase from baseline of 200 mL or more in PVR urine volume at any time after the initial toxin treatment (none with placebo). The proportion of patients who initiated CIC at any time during treatment cycle 1 was 6.1% versus none in the placebo group; for over half the patients who initiated CIC (10 of 17), the duration of CIC was 6 weeks or less. This value is lower than those reported in previous studies on IDO. In the study of Nitti and colleagues (2013b), discontinuation rates because of adverse effects were low in both the onabotulinumtoxinA (1.8%) and in the placebo (1.4%) groups.

Visco and colleagues (2012) performed a double-blind, double placebo-controlled, randomized trial (the ABC trial) in women with idiopathic UI. The participants were randomly assigned for a 6-month period to daily oral antimuscarinic medication (solifenacin, 5 mg initially, with possible escalation to 10 mg and, if necessary, subsequent switch to trospium ER, 60 mg) plus one intradetrusor injection of saline or one intradetrusor injection of

100 U of onabotulinumtoxinA plus daily oral placebo. The authors concluded that oral antimuscarinic therapy and onabotulinumtoxinA by injection were associated with similar reductions in the frequency of daily episodes of UI. The group receiving onabotulinumtoxinA was less likely to have dry mouth and more likely to have complete resolution of UI but had higher rates of transient urinary retention and urinary tract infections.

Capsaicin and Resiniferatoxin (Vanilloids). There is a rationale for the use of intravesical vanilloids (capsaicin and resiniferatoxin [RTX]) to suppress DO and urgency without DO. Results have not been consistent, and practical application has been a hurdle.

This subject is covered in detail on the Expert Consult website.

KEY POINTS: TOXINS FOR OVERACTIVE BLADDER

- Intradetrusor injections of onabotulinumtoxinA have been shown to be effective in the treatment of NDO and IDO as well as OAB symptoms without DO. The mechanism of action seems to be through both efferent and afferent decreases in the release of transmitter(s) substance(s). The doses used are different for neurogenic and idiopathic conditions. A potential complication in patients with voluntary voiding is urinary retention, and all such patients should be informed of this risk.
- There is a definite rationale for the use of intravesical capsaicin and RTX (vanilloids) for the treatment of patients with DO. Alcoholic capsaicin solution is extremely irritating, and RTX is much less pungent. There have been positive clinical trials with RTX, although some negative results occur as well. At the present time, this is not commonly used.

Estrogens for Urgency Urinary Incontinence and Overactive Bladder Symptoms

Estrogen has been used to treat postmenopausal urgency and urgency incontinence for many years, but there have been few controlled trials to confirm that it is of benefit (Hextall, 2000). A double-blind multicenter study of 64 postmenopausal women with "urge syndrome" failed to show efficacy (Cardozo et al, 1998). All women underwent pretreatment urodynamic investigation to ensure that they had either "sensory" urgency or DO. They were randomized to treatment with oral estriol 3 mg daily or placebo for 3 months. Compliance with therapy was confirmed by a significant improvement in the maturation index of vaginal epithelial cells in the active but not the placebo group. Estriol produced subjective and objective improvements in urinary symptoms but was not significantly better than placebo.

Another RCT from the same group using 25-mg estradiol implants confirmed the previous findings (Rufford et al, 2003), and furthermore found a high complication rate in the estradiol-treated patients (vaginal bleeding).

Symptoms of OAB increase in prevalence with increasing age, and LUTS and recurrent urinary tract infections are commonly associated with urogenital atrophy. Although the evidence supporting the use of estrogens in LUT dysfunction remains controversial, there are considerable data to support their use in urogenital atrophy, and the vaginal route of administration correlates with better symptom relief by improvement in vaginal dryness, pruritus, and dyspareunia, greater improvement in cytologic findings, and higher serum estradiol levels (Cardozo et al, 1998). Overall, vaginal estradiol has been found to be the most effective in reducing patient symptoms, although conjugated estrogens produced the most extensive cytologic change and the greatest increase in serum estradiol and estrone. The most recent meta-analysis of intravaginal estrogen treatment in the management of urogenital atrophy was reported by Suckling and colleagues (2003). Overall, 16 trials including 2129 women were analyzed,

and intravaginal estrogen was found to be superior to placebo in terms of efficacy, although there were no differences among types of formulation. Fourteen trials compared safety among the different vaginal preparations and found a higher risk of endometrial stimulation with conjugated equine estrogens (CEE) as compared with estradiol.

Thus, theoretically there could be a role for combination treatment with an antimuscarinic agent and vaginal estrogen in postmenopausal women. However, the two clinical trials that have been reported to date differ in their outcomes. Tseng and colleagues (2009) showed superior efficacy in terms of symptom improvement for OAB when tolterodine was used with vaginal estrogen cream as opposed to tolterodine alone. However, Serati and colleagues (2009) found no difference between tolterodine with or without topical estrogen in women with symptomatic DO.

Evidence Regarding Estrogens and Incontinence from Large Clinical Trials. The Heart and Estrogen/Progestin Replacement Study (HERS) included 763 postmenopausal women under the age of 80 years with CHD and intact uteri (Grady et al, 2001). It was designed to evaluate the use of estrogen in secondary prevention of cardiac events. In a secondary analysis, 1525 participants who reported at least one episode of incontinence per week at baseline were included. Participants were randomly assigned to 0.625 mg of conjugated estrogens plus 2.5 mg of medroxyprogesterone acetate (MPA) in one tablet ($n = 768$) or placebo ($n = 757$) and were followed for a mean of 4.1 years. Severity of incontinence was classified as improved, unchanged, or worsened. The results showed that incontinence improved in 26% of the women assigned to placebo compared with 21% assigned to hormones, whereas 27% of the placebo group worsened compared with 39% of the hormone group ($P = .001$). This difference was evident by 4 months of treatment, for both UI and SUI. The number of incontinence episodes per week increased an average of 0.7 in the hormone group and decreased by 0.1 in the placebo group ($P < .001$). The authors concluded that daily oral estrogen plus progestogen therapy was associated with worsening UI in older postmenopausal women with weekly incontinence and did not recommend this therapy for treatment of incontinence. However, it is possible that the progestogen component may have had an influence on the results of this study.

The Women's Health Initiative (WHI) was a multicenter double-blind placebo-controlled randomized clinical trial of menopause hormone therapy in 27,347 postmenopausal women aged 50 to 79 years enrolled from 1992 to 1998; UI symptoms were known in 23,296 participants at baseline and 1 year (Hendrix et al, 2005). The women were randomized based on hysterectomy status to active treatment or placebo. Those with a uterus were given 0.625 mg of conjugated equine estrogen (CEE) per day plus 2.5 mg of MPA per day (CEE + MPA), whereas those who had undergone hysterectomy received estrogen alone (CEE). At 1 year, hormone therapy was shown to increase the incidence of all types of UI in women who were continent at baseline. The risk was highest for SUI, followed by mixed UI. The combination of CEE and MPA had no significant effect on development of urge UI, but CEE alone increased the risk. For those women experiencing UI at baseline, frequency of micturition worsened in both active groups. Quantity of UI worsened at 1 year in both active groups. Those women receiving hormone therapy were more likely to report that UI limited their daily activities at 1 year. Thus, based on this secondary analysis of data from a huge study, CEE alone or in combination with MPA after 1 year of therapy was shown to increase the risk of UI in continent menopausal women and worsen UI in those incontinent at baseline.

The Nurses' Health Study (Grodstein et al, 2004) was a biennial postal questionnaire starting in 1976. In the study, 39,436 postmenopausal women aged 50 to 75 years who reported no urinary leakage at the start of the study were followed up for 4 years to identify incident cases of UI; 5060 women with occasional and 2495 with frequent incontinence were identified. The risk of developing UI was increased in postmenopausal women taking hormones compared with women who had never taken hormones.

Rationale for Intravesical Vanilloids. The rationale for intravesical vanilloid application in patients with DO is the demonstration that capsaicin, following bladder C-fiber desensitization, suppresses involuntary detrusor contractions dependent on a sacral micturition reflex (de Groat, 1997). The C-fiber micturition reflex is usually inactive, but it was shown that it is enhanced in patients with chronic spinal cord lesions above sacral segments (de Groat, 1997) in those with chronic BOO (Chai et al, 1998) and in those with IDO (Silva et al, 2002). In the bladders of NDO patients, the enhancement of the micturition reflex is accompanied by an increase in the number of suburothelial C-fibers expressing TRPV1 (Brady et al, 2004a). It is curious that NDO patients who responded better to intravesical RTX exhibited a significant decrease in the density of TRPV1 immunoreactive fibers, whereas nonresponders experienced a nonsignificant variation (Brady et al, 2004a). A decrease in TRPV1 expression in urothelial cells of NDO patients was also demonstrated after intravesical application of RTX (Apostolidis et al, 2005a, 2005b, 2006).

Changes in suburothelial C-fiber innervation expressing neuropeptides (Smet et al, 1997) or TRPV1 (Liu and Kuo, 2007) were also reported in patients with sensory urgency. In IDO patients, responders to intravesical RTX are closely associated with the overexpression of the receptor in the bladder mucosa (Liu and Kuo, 2007). In women with sensory urgency, TRPV1 mRNA expressed in trigonal mucosa was not only increased but also inversely correlated with the bladder volume at first sensation of filling during cystometry, further indicating that TRPV1 may play a role in premature bladder sensation (Liu et al, 2007).

Intravesical Capsaicin. Intravesical capsaicin for NDO was studied in six noncontrolled (Fowler et al, 1992b, 1994; Geirsson et al, 1995; Das et al, 1996; Cruz et al, 1997; De Ridder et al, 1997) and one controlled (de Sèze et al, 1998) clinical trial. Capsaicin was dissolved in 30% alcohol, and 100 to 125 mL (or half of the bladder capacity if lower than that volume) of 1- to 2-mM solutions were instilled into the bladder and left in contact with the mucosa for 30 minutes. Best clinical results were found in patients with incomplete spinal cord lesions, in whom clinical improvement could be observed in up to 70% to 90% (Fowler et al, 1994; Cruz et al, 1997; De Ridder et al, 1997). In patients with complete spinal cord lesions, the success rate was much lower (Geirsson et al, 1995).

Only one small randomized controlled study compared capsaicin against 30% ethanol, the vehicle solution. Ten patients received capsaicin; a significant regression of the incontinence and urge sensation was found. In contrast, only 1 of the 10 patients who received ethanol had clinical improvement (de Sèze et al, 1998).

The pungency of alcoholic capsaicin solutions has prevented the widespread use of this compound. In particular, the possibility of triggering autonomic dysreflexia with capsaicin, especially in patients with higher spinal cord lesions, has progressively restrained its use. The relevance of capsaicin might, however, be back, with a recent report by de Sèze and colleagues (2006), who used a new capsaicin formulation. They conducted a double-blind placebo-controlled study with a glucidic solution of capsaicin in 33 NDO patients. The glucidic capsaicin-treated group showed improvement both in symptoms and in urodynamic parameters above the comparator arm. The global tolerance of this new capsaicin formulation was excellent (de Sèze et al, 2006).

Resiniferatoxin in Neurogenic Detrusor Overactivity. RTX has the advantage over capsaicin in being much less pungent (Cruz et al, 1997). Intravesical RTX application in NDO patients was evaluated in five small open-label studies (Cruz et al, 1997; Lazzeri et al, 1997, 1998; Silva et al, 2000; Kuo, 2003). Different RTX concentrations, 10 nM, 50 nM, 100 nM, and 10 μ M, were tested. RTX brought a rapid improvement or disappearance of UI in up to 80% of the selected patients and a 30% decrease in their daily urinary frequency. Furthermore, RTX also increased the volume to FDC and maximal cystometric capacity. In general, in patients receiving 50- or 100-nM RTX, the effect was long-lasting, with a duration of more than 6

months being reported. In patients treated with 10- μ M doses, transient urinary retention sometimes occurred (Lazzeri et al, 1998).

In a placebo-controlled study, the urodynamic effects of RTX in NDO patients were specifically evaluated. Only in the RTX arm, a significant increase in FDC and maximal cystometric capacity was found (Silva et al, 2005). RTX also caused a significant improvement in urinary frequency and incontinence (Silva et al, 2005).

RTX 600 nM was compared against BoNTA (Botox, 300 U) in a study involving 25 patients with NDO from chronic SCI. Both neurotoxins were capable of significantly reducing the number of daily incontinence episodes and improving maximum bladder capacity, although BoNTA turned out to be more effective.

Resiniferatoxin in Idiopathic Detrusor Overactivity. The first study with intravesical RTX in IDO patients was designed as a proof-of-concept study and involved 13 patients. Intravesical RTX 50 nmol/L was associated with an improvement in volume to FDC from 170 \pm 109 mL to 440 \pm 153 mL at 30 days, and to 391 \pm 165 mL at 90 days. An increase in mean MCC from 291 \pm 160 mL to 472 \pm 139 mL at 30 days and to 413 \pm 153 mL at 90 days was also observed. These improvements were accompanied by a decrease in episodes of urgency incontinence and of daily frequency (Silva et al, 2002). Subsequent small open-label studies confirmed these observations using either a single high dose (50 to 100 nM) or multiple low doses (10 nM) (Kuo, 2003; Dinis et al, 2004; Kuo, 2005b).

The effect of RTX on refractory IDO was evaluated in two randomized clinical trials (Kuo et al, 2006; Rios et al, 2007). Kuo and colleagues (2006) randomized 54 patients to receive four weekly instillations of a low-concentration RTX solution (10 nmol/L) or the vehicle solution, 10% ethanol in saline. Three months after completing the four intravesical treatments, the RTX-treated group had 42.3% and 19.2% of patients feeling much better or improved, respectively. This was significantly more than in the placebo group—14.2% and 7.1%, respectively. At 6 months, treatment remained effective in 50% of patients in the RTX group but only in 11% in the placebo group (Kuo et al, 2006). Such clinical and urodynamic findings could not be reproduced in another study in which patients were randomly assigned to receive a single intravesical dose of 100 mL of either RTX 50 nM or placebo. Patients were followed for only 4 weeks. During this period a single 50-nM intravesical dose of RTX was not better than placebo for the treatment of women with IDO and urgency incontinence (Rios et al, 2007).

Resiniferatoxin and Urgency. The involvement of bladder C fibers in IDO has led some investigators to explore the role of these sensory afferents in the genesis of urgency. In a noncontrolled study involving 12 male patients with LUTS associated with BPH, mean IPSS halved after intravesical administration of RTX (50 nmol/L). The decrease in IPSS was largely the result of improvements in scores related to urgency, in addition to improvement in nocturia and frequency (Dinis et al, 2005). In another open-label study, 15 patients with intractable urgency and frequency, with or without urgency incontinence or bladder pain or discomfort, and without urodynamic evidence of DO received one single administration of 50-nM RTX solution. A trend toward an improvement of urgency was noticed (Apostolidis et al, 2006).

In a quasi-randomized study, 23 OAB patients with refractory urgency entered a 30 day run-in period in which medications influencing the bladder function were interrupted. At the end of this period, patients filled out a 7-day bladder diary. Then patients underwent instillation of 100 mL of 10% ethanol in saline (vehicle solution), and 30 days later a second 7-day diary was collected. Finally, patients underwent instillation of 100 mL of 50-nM RTX in 10% ethanol in saline, and additional bladder diaries were collected at 1 and 3 months. After vehicle instillation, the mean number of episodes of urgency per week was 56 \pm 11. At 1 and 3 months after RTX instillation, the number of episodes of urgency decreased to 39 \pm 9 (P = .002) and 37 \pm 6 (P = .02), respectively (Silva et al, 2007).

After cessation of hormone therapy, there was a decreased risk of incontinence such that 10 years after stopping hormones the risk was identical in women who had and who never had taken hormone therapy.

The most recent meta-analysis of the effect of estrogen therapy on the LUT was performed by [Cody and colleagues \(2009\)](#) and is notable because the conclusions are starkly different from those drawn from the previous review ([Moehrer et al, 2003](#)). Overall, 33 trials were identified, including 19,313 incontinent women (1262 involved in trials of local administration), of whom 9417 received estrogen therapy. **Systemic administration (of unopposed oral estrogens—synthetic equine estrogens and CEEs) resulted in worse incontinence than placebo**, although this was heavily influenced by the size of the WHI study ([Hendrix et al, 2005](#)). **With regard to combination therapy, there was a similar worsening effect on incontinence when compared with placebo. There was some evidence suggesting that the use of local estrogen therapy may improve incontinence, and overall there were one to two fewer voids in 24 hours and less frequency and urgency.**

The authors concluded that local estrogen therapy for incontinence may be beneficial, although there was little evidence of long-term effect. The evidence would suggest that systemic hormone replacement using CEEs may make incontinence worse. In addition, they reported that there are too few data to comment reliably on the dose type of estrogen and route of administration.

Estrogen has an important physiologic effect on the female LUT, and its deficiency is an etiologic factor in the pathogenesis of a number of conditions. However, the use of estrogen either alone or in combination with progestogen has yielded poor results. **The current level 1 evidence against the use of estrogen for the treatment of UI comes from studies powered to assess their benefit in the prevention of cardiovascular events**, and therefore the secondary analyses have been based only on self-reported symptoms of urinary leakage without any objective data. Despite this, all of these large RCTs show a worsening of preexisting UI, both SUI and UI, and an increased new incidence of UI with both estrogen and estrogen plus progestogen. However, the majority of subjects in all of these studies were taking combined equine estrogen, and this may not be representative of all estrogens taken by all routes of administration.

In a systematic review of the effects of estrogens for symptoms suggestive of OAB, the conclusion was that estrogen therapy may be effective in alleviating OAB symptoms, and that local administration may be the most beneficial route of administration ([Cardozo et al, 2004c](#)). It is quite possible that the reason for this is that the symptoms of urinary urgency, frequency, and urge incontinence may be a manifestation of urogenital atrophy in older postmenopausal women rather than a direct effect on the LUT ([Robinson and Cardozo, 2003](#)). Although there is good evidence that the symptoms and cytologic changes of urogenital atrophy may be reversed by low-dose (local) vaginal estrogen therapy, there is currently no evidence that estrogens with or without progestogens should be used in the treatment of UI.

KEY POINTS: HORMONES AND URINARY INCONTINENCE

- Conclusions reached in a number of studies have been that (1) daily oral estrogen plus progestogen therapy is associated with worsening UI in older postmenopausal women with weekly incontinence, and (2) CEE alone or in combination with MPA increases the risk of UI in continent menopausal women and worsens UI in those incontinent at baseline.
- There is some evidence suggesting that local (vaginal) therapy with estrogen may improve OAB symptoms in postmenopausal women, perhaps by its reversal of urogenital atrophy.

Other Hormones and Desmopressin

Progesterone and progestogens are thought to increase the risk of UI. LUTS, especially SUI, have been reported to increase in the progestogenic phase of the menstrual cycle ([Hextall et al, 2001](#)). In similar studies, progesterone has been shown to increase β -AR activity, leading to a decrease in the urethral closure pressure in female dogs ([Raz et al, 1973](#)). However, in the WHI there appeared to be no difference whether or not progestin was given in addition to estrogen ([Hendrix et al, 2005](#)).

Selective estrogen receptor modulators (SERMS) have been reported to have varying effects. Each of the SERMS has receptor ligand conformations that are unique and have both estrogenic and antiestrogenic effects. In the clinical trials of levormeloxifene, there was a fourfold increase in the incidence of incontinence, leading to cessation of the clinical trial ([Hendrix et al, 2001](#)). However, raloxifene has not been shown to have any effect at all on UI ([Waetjen et al, 2004](#)). There are no reported clinical trials evaluating the effect of androgens, and in particular testosterone, on UI in women.

Desmopressin. The endogenous hormone vasopressin (also known as *antidiuretic hormone*) has two main functions: It causes contraction of vascular smooth muscle, and it stimulates water reabsorption in the renal medulla. These functions are mediated by two specific vasopressin receptors, of which there are two major subtypes, namely the V_1 and V_2 receptors. The V_2 subtype is particularly important for the antidiuretic effects of vasopressin. A genetic or acquired defect in making and secreting vasopressin leads to central diabetes insipidus, and genetic defects in the gene encoding the V_2 receptor can cause nephrogenic diabetes insipidus ([Insel et al, 2007](#)). Accordingly, decreased vasopressin levels are believed to be important in the pathophysiology of some forms of polyuria, specifically NP, which can lead to symptoms such as nocturia ([Matthiesen et al, 1996](#); [Weiss et al, 2011a](#)). Nocturia is currently defined by the ICS as the complaint that an individual has to wake at night one or more times to void. It is, however, “an underreported, understudied, and infrequently recognized problem in adults” ([Weiss et al, 2011b](#)). Nocturia leads to decreased QoL ([Kupelian et al, 2011](#)) and has been associated with both increased morbidity and mortality ([Nakagawa et al, 2010](#); [Kupelian et al, 2012](#)). Although it remains largely unknown which fraction of patients with nocturia can indeed be explained by too little vasopressin, the presence of NP in the absence of behavioral factors explaining it (such as excessive fluid intake) is usually considered as an indication that a (relative) lack of vasopressin may exist ([Bosch and Weiss, 2010](#); [Weiss et al, 2011b](#)).

Based on these considerations, vasopressin-receptor agonists have been used to treat nocturia, both in children and in adults. Desmopressin is the most common vasopressin analogue used to treat nocturia. Desmopressin shows selectivity for antidiuretic over vasopressor effects. It has a more powerful and longer-lasting antidiuretic action than vasopressin. It is available in formulations for oral, parenteral, and nasal administration. It has a fast onset of action, with urine production decreasing within 30 minutes of oral administration ([Rittig et al, 1998](#)). Because symptomatic hyponatremia with water intoxication, which is the only serious adverse event reported in children, occurred after intranasal or intravenous administration of desmopressin ([Thumfart et al, 2005](#); [Robson et al, 2007](#); [Van de Walle et al, 2010](#)), the FDA and the European Medicines Agency (EMA) removed the indication for the treatment of primary nocturnal enuresis from all intranasal preparations of desmopressin. An oral lyophilisate formulation (MELT) requiring no concomitant fluid intake is currently available. In a recent open-label, randomized, crossover study, desmopressin MELT was shown to have similar levels of efficacy and safety at lower doses than the tablet formulation of desmopressin in children. A recent study confirmed the superior pharmacodynamic characteristics of desmopressin MELT to desmopressin tablets ([De Guchtenaere et al, 2011](#)).

The use of desmopressin in children with nocturnal enuresis was comprehensively reviewed by [Glazener and Evans in 2002](#). These authors evaluated 47 RCTs involving 3448 children, of whom 2210

received desmopressin. According to the analysis, desmopressin was effective relative to placebo in reducing bedwetting; a dose of 20 μ g resulted in a reduction of 1.34 wets per night (95% CI 1.11 to 1.57), and children were more likely to become dry with desmopressin (98%) than with placebo (81%). However, there was no difference between desmopressin and placebo after discontinuation of treatment, indicating that **desmopressin suppresses the symptom of enuresis but does not cure the underlying cause**. In addition, not all children responded sufficiently to desmopressin monotherapy. The combination of desmopressin and an enuresis alarm resulted in a greatly improved short-term success rate and decreased relapse rates (Alloussi et al, 2011). The combination of desmopressin and antimuscarinics resulted in better short- and long-term success rates as well as a lower relapse rate than desmopressin alone (Austin et al, 2008; Alloussi et al, 2009). For nonresponders to desmopressin, replacement of desmopressin with other medications such as tricyclic antidepressants or loop diuretics could be of benefit, whereas muscarinic-receptor antagonists may be ineffective in such children (De Guchtenaere et al, 2007; Neveus and Tullus, 2008).

Other studies have explored a possible treatment role for desmopressin in the treatment of nocturia in adults. A search for these studies in Medline using the terms *desmopressin* and *nocturia* was performed and limited to clinical studies of de novo nocturia, that is, those that excluded subjects in whom childhood enuresis persisted into adulthood. Several previous studies investigated the use of desmopressin for the treatment of nocturia in the context of multiple sclerosis (Eckford et al, 1994, 1995). One study with single-dose administration reported a reduction in NP, but by design did not assess nocturia (Eckford et al, 1995). Three placebo-controlled double-blind studies with small patient numbers (16 to 33 patients total per study) reported a significant reduction in nocturia (Hilton et al, 1983; Eckford et al, 1994; Valiquette et al, 1996). Other controlled studies of similar size, most with a crossover design, used micturition frequency within the first 6 hours after desmopressin administration rather than nocturia as their primary end point. These studies consistently reported that desmopressin treatment for up to 2 weeks was efficacious (Kinn and Larsson, 1990; Fredrikson, 1996; Hoverd and Fowler, 1998). Although desmopressin treatment was generally well tolerated, 4 of 17 patients in one study discontinued treatment because of asymptomatic or minimally symptomatic hyponatremia (Valiquette et al, 1996). Accordingly, **desmopressin is now registered for the treatment of nocturia in multiple sclerosis patients** (Cvetkovic and Plosker, 2005). In a small open-label study, desmopressin was also reported to reduce NP in SCI patients (Zahariou et al, 2007).

Further studies have explored the use of desmopressin in adults with nocturia in the apparent absence of neurologic damage. The recruited patient populations were based on different criteria, including having at least two nocturia episodes per night or having NP. Earlier studies mostly used a desmopressin dose of 20 μ g given either orally (Asplund et al, 1999) or intranasally (Hilton and Stanton, 1982; Cannon et al, 1999), and tended to be very small (25 or fewer patients). Later studies, as part of the NOCTUPUS program, were considerably larger, involving a total of 1003 screened patients, and higher oral doses (0.1–0.4 mg) were administered for a period of 3 weeks of double-blind treatment in adults (Mattiasson et al, 2002; Lose et al, 2004; van Kerrebroeck et al, 2007). A total of 632 patients entered the dose-titration phase and 422 patients entered the double-blind phase of the three NOCTUPUS trials. To counter the argument that the study was performed in desmopressin responders after the dose titration phase, all patients in the NOCTUPUS trials were washed out after the dose-titration phase, and to be randomized the patients were required to be returned to baseline nocturnal diuresis before inclusion in the double-blind phase. The trials showed that oral desmopressin (0.1, 0.2, or 0.4 mg) is effective in both men and women aged 18 years or older with nocturia. The number of nocturnal voids decreased from 3 to 1.7 in the desmopressin group compared with 3.2 to 2.7 in the placebo group. In women, the number of nocturnal voids in the desmopressin group decreased from 2.92 to 1.61, whereas that in the placebo group decreased from 2.91 to 2.36. When clinical response was

defined as 50% or greater reduction in nocturnal voids from baseline, 34% of men experienced clinical response with desmopressin, compared with 3% of men who received placebo. In women, 46% of desmopressin-treated patients experienced a clinical response, compared with 7% of patients on placebo.

The efficacy of desmopressin for the treatment of nocturia was confirmed in a long-term (10 to 12 months) open-label study involving 249 patients, which was an extension of the randomized studies in known desmopressin responders. However, a rebound effect was seen when treatment was withdrawn, confirming the association between continued treatment and response (Lose et al, 2004). An open-label pilot study in a nursing home setting also reported that desmopressin had beneficial effects (Johnson et al, 2006).

Around 75% of community-dwelling men and women with nocturia (two or more voids per night) have NP (Rembratt et al, 2003; Swithinbank et al, 2004). The key urologic factors most relevant to nocturia are NP and OAB in women (Irwin et al, 2008) and NP and BPH in men. About 74% of women with OAB have nocturia, and 62% of patients with OAB and nocturia have NP. Among men with nocturia, 83% have NP, 20% have NP alone, and 63% have NP in combination with another factor such as a small nocturnal bladder capacity or BOO (Chang et al, 2006). Therefore, desmopressin combination therapy with α_1 -AR antagonists and/or antimuscarinics should be considered for patients with treatment-resistant nocturia. Seventy-three percent of α_1 -AR antagonist-resistant BPH patients experienced a 50% or greater reduction in nocturnal voids with oral desmopressin (Yoong et al, 2005). A randomized, double-blind, placebo-controlled study evaluating the long-term (1, 3, 6, and 12 months) efficacy and safety of low-dose (0.1 mg) oral desmopressin in elderly (65 years or older) patients reported that low-dose oral desmopressin led to a significant reduction in the number of nocturnal voids and nocturnal urine volume in patients with BPH (Wang et al, 2011).

Because nocturia can be caused by different factors, several studies have investigated whether desmopressin may be beneficial in patients with other symptoms in addition to nocturia. In a small, nonrandomized pilot study of men believed to have BPH, desmopressin was reported not only to improve nocturia, but also to reduce the overall IPSS (Chancellor et al, 1999). An exploratory, placebo-controlled double-blind study in women with daytime UI reported that intranasal administration of 40 μ g of desmopressin increased the number of leakage-free episodes 4 hours after drug administration (Robinson et al, 2004). One double-blind, placebo-controlled pilot study in patients with OAB treated with 0.2 mg of oral desmopressin reported a reduction in voids along with an improvement in QoL (Hashim et al, 2009). Although these data indicate that desmopressin may be effective in treating LUT dysfunction not limited to nocturia, they are too sparse to allow treatment recommendations.

Desmopressin was well tolerated in all the studies and resulted in significant improvements compared with placebo in reducing nocturnal voids and increasing the hours of undisturbed sleep. There was also an improvement in QoL. However, one of the main clinically important side effects of desmopressin use is hyponatremia. Hyponatremia can lead to a variety of adverse events ranging from mild headache, anorexia, nausea, and vomiting to loss of consciousness, seizures, and death. Hyponatremia usually occurs soon after treatment is initiated. The **risk of hyponatremia appears to increase with age, cardiac disease, and increasing 24-hour urine volume** (Rembratt et al, 2006). Based on a meta-analysis, the incidence is around 7.6% (Weatherall, 2004). **Increased age and female gender are well-known risk factors** for the development of desmopressin-induced hyponatremia. Bae and colleagues (2007) assessed the effects of long-term oral desmopressin on serum sodium and baseline antidiuretic hormone secretion in 15 elderly male patients with severe nocturia (more than three voids nightly) who did not show hyponatremia within 7 days of administration of 0.2 mg desmopressin. Desmopressin (0.2 mg) was administered orally nightly for 1 year. Before and 1 month after the 1-year medication 24-hour circadian studies were performed to

monitor changes in antidiuretic hormone. Every 3 months during the 1-year medication period, serum changes and timed urine chemistry were monitored. The results showed that long-term desmopressin administration gradually decreased serum sodium and induced statistically, but not clinically significant, hyponatremia after 6 months of treatment. Administration of desmopressin for 1 year did not affect baseline antidiuretic hormone secretion. The authors recommended that for long-term desmopressin administration, serum sodium should be assessed regularly, at least every 6 months.

A recent focus has been on exploring gender differences in the antidiuretic response to desmopressin. Juul and colleagues (2011) found an increasing incidence of hyponatremia with increasing dose; and at the highest dose level of 100 µg, decreases in serum sodium were approximately twofold greater in women over 50 years of age than in men. The gender difference could not be explained by pharmacokinetic differences. They calculated an ED₅₀ ratio for men/women to be 2.7 (1.3 to 8.1). A new dose recommendation stratified by gender was suggested in the treatment of nocturia: For men, 50 to 100 µg MELT was suggested to be an efficacious and safe dose, and for women a dose of 25 µg MELT was recommended as efficacious with no observed incidences of hyponatremia. Initiation of desmopressin is currently not indicated for patients aged 65 years or older. The mechanisms behind desmopressin-induced hyponatremia are well understood, and serum sodium monitoring at baseline and early during treatment of older patients for whom treatment with desmopressin is indicated can greatly reduce their risk of developing the condition. Other advice regarding treatment administration, such as restriction of evening fluid intake and adherence to the recommended administration regimen, should be followed to minimize the risk of hyponatremia (Vande Walle et al, 2007).

Desmopressin is useful for patients with nocturia as well as for children with nocturnal enuresis. The drug has been proven to be well tolerated and effective in several randomized, placebo-controlled trials and is recommended as a first-line treatment (either as monotherapy or in combination with other agents) with proper precaution for patients who have been appropriately evaluated and whose nocturia is related to NP, whether or not this is accompanied by BPH or OAB. For assessment, see Table 79-3. A rapidly acting, quickly metabolized preparation with minimal risk of hyponatremia would obviously be useful for the treatment of nocturia in adults and could have application for “spot usage” for a limited time period in patients with OAB.

KEY POINTS: DESMOPRESSIN IN NOCTURNAL POLYURIA

- Desmopressin is an analogue of vasopressin that shows selectivity for antidiuretic effects (water reabsorption in the renal medulla) over vasopressor effects. It suppresses the symptom of nocturnal enuresis in children without curing the underlying cause. It has been used in a number of studies in patients with and without neurogenic disease for the treatment of nocturia. Results in general have been statistically significant improvements in nocturnal voids and hours of undisturbed sleep.
- The most important adverse event is hyponatremia, an increased risk of which is seen with age, female gender, cardiac disease, and increased 24-hour urine volume. Some regimen of serum sodium monitoring is indicated along with other advice designed to minimize the risk of hyponatremia.

Drug Treatment of Overactivity in Augmented or Intestinal Neobladders

With regard to the subject of overactivity in bowel augmented or intestinal neobladders, Andersson and colleagues (1992) reviewed

this subject and its pharmacologic treatment. They noted a few instances of positive results with drugs given systematically, but locally applied agents were believed to offer more promise. Pure antimuscarinic agents had produced few good results, either locally or systemically. Oxybutynin had shown some good results with local therapy but poor results with systemic therapy. The α- and β-AR agonists had shown little or no effects. Other possibilities mentioned included opioid agonists (diphenoxylate and loperamide), calcium antagonists, potassium channel openers, and NO donors. Apostolidis and colleagues (2007) reported a case of successful treatment with botulinum toxin A after failed augmentation ileocystoplasty.

Future Possibilities

Please see the Expert Consult website for this section.

Increasing Outlet Resistance

Many factors seem to be involved in the pathogenesis of SUI: urethral support, vesical neck function, and function of the nerves and musculature of the bladder, urethra, and pelvic floor (DeLancey, 1997; Mostwin et al, 2005; Koelbl et al, 2009; Chapple and Milsom, 2012). Anatomic factors cannot be treated pharmacologically. However, women with SUI have lower resting urethral pressures than age-matched continent women (Henriksson et al, 1979; Hilton et al, 1983), and because it seems likely that there is a reduced urethral closure pressure in most women with SUI, it seems logical to increase urethral pressure to improve the condition.

Factors that may contribute to urethral closure include tone of urethral smooth and striated muscle and the passive properties of the urethral lamina propria, in particular its vasculature. The relative contribution to intraurethral pressure of these factors is still subject to debate. However, there is ample pharmacologic evidence that a substantial part of urethral tone is mediated through stimulation of α-ARs in the urethral smooth muscle by released NA (Andersson, 1993; Andersson and Wein, 2004). A contributing factor to SUI, mainly in elderly women with lack of estrogen, may be lack of mucosal function. The pharmacologic treatment of SUI aims at increasing intraurethral closure forces by increasing the tone in the urethral smooth and striated muscles. Several drugs may contribute to such an increase (Andersson, 1988; Zinner et al, 2004), but relative lack of efficacy and/or side effects have limited their clinical use. For assessments, see Table 79-4.

Drugs Used for Treatment of Stress Incontinence In Women

Estrogens

Estrogens and the Continence Mechanism. The estrogen-sensitive tissues of the bladder, urethra, and pelvic floor all play an important role in the continence mechanism. For women to remain continent, the urethral pressure must exceed the intravesical pressure at all times except during micturition. The urethra has four estrogen-sensitive functional layers, all of which have a role in the maintenance of a positive urethral pressure: (1) epithelium, (2) vasculature, (3) connective tissue, and (4) muscle.

Two types of estrogen receptors (α and β) have been identified in the trigone of the bladder, urethra, and vagina, as well as in the levator ani muscles and fascia and ligaments within the pelvic floor (Smith et al, 1990; Copas et al, 2001; Gebhardt et al, 2001). After menopause, estrogen receptor α has been shown to vary depending on exogenous estrogen therapy (Fu et al, 2003). In addition, exogenous estrogens affect the remodeling of collagen in the urogenital tissues, resulting in a reduction of the total collagen concentration with a decrease in the cross-linking of collagen in both continent and incontinent women (Keane et al, 1997; Falconer et al, 1998). Studies in both animals and humans have shown that estrogens also increase vascularity in the periurethral plexus, which can be measured as vascular pulsations on urethral pressure profilometry (Versi and Cardozo, 1986; Robinson et al, 1996; Endo et al, 2000).

Peripherally Acting Drugs

Vitamin D₃-Receptor Analogues. It is well known that vitamin D affects skeletal muscle strength and functional efficiency, and vitamin D insufficiency has been associated with notable muscle weakness. The levator ani and coccygeus skeletal muscles are critical components of the pelvic floor and may be affected by vitamin D nutritional status. Weakened pelvic floor musculature is thought to be associated with the development of UI and fecal incontinence symptoms. Aging women are at increased risk for both pelvic floor dysfunction and vitamin D insufficiency; to date, only small case reports and observational studies have shown an association between insufficient vitamin D and pelvic floor dysfunction symptom severity (Parker-Autry et al, 2012). Rat and human bladders were shown to express receptors for vitamin D (Crescioli et al, 2005), which makes it conceivable that the bladder may also be a target for vitamin D. Analogues of vitamin D₃ have also been shown to inhibit BPH cell proliferation and to counteract the mitogenic activity of potent growth factors for BPH cells (Crescioli et al, 2002, 2003, 2004). Experiments in rats with bladder outflow obstruction (Schröder et al, 2006) showed that one of the analogues, BXL-628, at nonhypercalcemic doses did not prevent bladder hypertrophy, but reduced the decrease in contractility of the bladder smooth muscle that occurred with increasing bladder weight (Schröder et al, 2006). The mechanism of action for the effects has not been clarified. However, elocalcitol was shown to have an inhibitory effect on the RhoA/Rho-kinase pathway (Morelli et al, 2007). Upregulation of this pathway has been associated with bladder changes associated with diabetes, outflow obstruction, and DO (Peters et al, 2006; Christ and Andersson, 2007). In rats with outflow obstruction, previous elocalcitol treatment improved the effects of tolterodine on bladder compliance (Streng et al, 2012). It was suggested that in rats, elocalcitol exerted additional beneficial actions on outflow obstruction-induced functional changes during the filling phase of micturition. If this finding is valid in humans, combined therapy with the drug would be of value.

The effect of elocalcitol on prostate volume was evaluated in patients with BPH, and it was found that elocalcitol was able to arrest prostate growth within 12 weeks in men aged 50 years or older with prostatic volume of 40 mL or greater (Colli et al, 2006). In an RCT enrolling 120 female patients with OAB in which the primary end point was an increase in the MVV, a significant increase versus placebo (22% vs. 11%) was demonstrated (Colli et al, 2007). The determination of whether or not vitamin D–receptor agonism (monotherapy or in combination) will be a useful alternative for the treatment of LUTS and OAB requires further RCTs. However, currently the development of the drug seems to be stopped (Tiwari, 2009).

Transient Receptor Potential Channel Antagonists. The TRP channel superfamily has been shown to be involved in nociception and mechanosensory transduction in various organ systems, and studies of the LUT have indicated that several TRP channels, including TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1, are expressed in the bladder and may act as sensors of stretch and/or chemical irritation (Araki et al, 2008; Everaerts et al, 2008; Andersson et al, 2010a; Araki, 2011). TRPV1 and TRPV4 channels have been found to be expressed in the urinary bladder (Tominaga et al, 1998; Birder et al, 2001; Gevaert et al, 2007). TRPV1 is present and active both in the urothelium and in the nerve fibers of several species including humans (Ji et al, 2002; Charrua et al, 2009b). TRPV4 was initially described in the urothelium of rodents and humans (Janssen et al, 2011). Coexpression of the two receptors was observed in 20% of rat urothelial cells (Kullmann et al, 2009). Recent observations indicate, however, that TRPV4 may also be expressed in bladder afferents. In fact, about 30% of L6 dorsal root ganglia neurons that project to the urinary bladder coexpress TRPV1 and TRPV4 (Cao et al, 2009). The physiologic meaning of this observation is unclear.

TRPV1 KO mice have a normal or quasi-normal phenotype. In awake animals, the only change detected in TRPV1 KO mice was a smaller volume per void when compared with wild-type (WT) controls (Birder et al, 2001). In cystometries performed under

anesthesia, the TRPV1 KO mice phenotype seems also very benign. Some studies reported that these animals have totally normal cystometric traces (Charrua et al, 2007). However, other studies showed that TRPV1 KO mice develop a few nonvoiding contractions preceding the voiding contraction (Birder et al, 2001; Frias et al, 2012). Accordingly, TRPV1 antagonists (GRC-6211) did not show any relevant effect on bladder activity of intact rodents (Charrua et al, 2009a). In contrast with TRPV1 KO mice, the micturition phenotype of TRPV4 KO animals is clearly abnormal. TRPV4 KO mice are incontinent, most probably because of incomplete bladder emptying (Gevaert et al, 2007). Cystometric studies carried out under physiologic conditions revealed that TRPV4 KO mice have a marked increase in the intercontraction interval when compared with WT littermates (Birder et al, 2002; Gevaert et al, 2007). Likewise, TRPV4 antagonists (HC-067047) decreased the frequency of bladder contractions and increased the intercontraction interval (Everaerts et al, 2010). These observations indicated that TRPV4 has a role in the control of the normal micturition reflex.

Indisputably, TRPV1 and TRPV4 have a role in the increase of micturition frequency associated with cystitis (Charrua et al, 2007; Everaerts et al, 2010). Whereas inflamed WT mice exhibit bladder hyperactivity and intense spinal Fos expression after different forms of bladder inflammation, including acetic acid or bacterial extracts, TRPV1 KO mice have normal cystometries and normal spinal c-Fos expression (Charrua et al, 2007). The same holds true for TRPV4. In fact, TRPV4 KO mice exhibit significantly lower voiding frequencies and larger voided volumes than WT after inflammation with cyclophosphamide (Everaerts et al, 2010).

The blockade of TRPV1 and TRPV4 with specific antagonist confirms the observations carried out in KO animals. As a matter of fact, the TRPV1 antagonist GRC-6211 and the TRPV4 antagonist HC-067047 both abolish the increase of micturition frequency associated with chemical cystitis (Charrua et al, 2009a; Everaerts et al, 2010). Systemic coadministration of TRPV1 and TRPV4 antagonist was more effective in treating the cystitis-induced increase of micturition frequency than the individual application of each antagonist (Avelino et al, 2013). In particular, the effect could be observed at very low doses of the TRPV1 and TRPV4 antagonists, which had no effect when given isolated. This observed effect might be the answer to overcome the eventual adverse events related to the application of some of these antagonists (Planells-Cases et al, 2011). Just to mention a few, TRPV1 antagonists are associated with hyperthermia and increased risk of cardiac ischemia (Avelino et al, 2013), and TRPV4 antagonists may eventually precipitate urinary retention and overflow incontinence (Gevaert et al, 2007).

It has long been known that TRPV1 is involved in the emergence of NDO after spinal cord transection (Avelino and Cruz, 2006). A TRPV1 antagonist, GRC-6211, has been shown to decrease reflex DO in rats after chronic spinal cord transection. With increasing doses, it was possible to obtain a total suppression of bladder activity (Santos-Silva et al, 2012).

There seem to be several links between activation of different members of the TRP superfamily and LUTS, DO, and OAB, and further exploration of the involvement of these channels in LUT function, normally and in dysfunction, may be rewarding. However, proof-of-concept studies in humans are still lacking.

Prostanoid-Receptor Agonists and Antagonists. Developments in the field of prostanoid receptors may open new possibilities for use of selective prostanoid-receptor antagonists for OAB and DO treatment (Aoki et al, 2009; Jones et al, 2009). There is evidence suggesting that PGE₂ contributes to the pathophysiology of OAB and DO: PGE₂ infused into the bladder induces DO in humans and animals and increases PGE₂ production in DO models, and there are high concentrations of PGE₂ in the urine of patients with OAB (McCafferty et al, 2008). PGE₂ is an agonist at EP receptors 1 to 4, all G protein coupled, which mediate its physiologic effects. Based on studies using KO mice and EP₁-receptor antagonists, it was suggested that the effects of PGE₂ on bladder function were mediated through EP₁ receptors (Schröder et al, 2004). EP receptors can be found on urothelium/suburothelium, in detrusor smooth muscle, and in intramural ganglia (Wang et al, 2008; Rahnama'i et al, 2010,

2011). Functionally, it has been proposed that modulation of bladder activity exerted via EP₁ receptors occurs via an afferent mechanism. Schröder and colleagues (2004) found no difference in urodynamic parameters between unobstructed EP₁ receptor KO and WT mice. However, EP₁ receptor KO mice did not respond to intravesical PGE₂ instillation, whereas WT mice developed DO. The lack of EP₁ receptor did not prevent bladder hypertrophy caused by partial bladder outflow obstruction, but after obstruction WT mice had pronounced DO, whereas this was negligible in EP₁ receptor KO mice.

Lee and colleagues (2008b) found that in normal rats a selective EP-receptor antagonist significantly increased bladder capacity, micturition volume, and micturition intervals. The antagonist significantly decreased the stimulatory effects of PGE₂ and decreased the frequency and amplitude of nonvoiding contractions in animals with BOO. It has also been shown that EP₃ receptor KO mice have a diminished response to bladder infusion of PGE₂ and demonstrate an enhanced bladder capacity under basal conditions (Jones et al, 2009). These findings suggest an important contribution for EP₃ receptors in the modulation of bladder function under physiologic conditions as well as under conditions of enhanced PGE₂ production evoking DO. Thus, EP₁ and EP₃ receptors may have a role in PGE₂-mediated DO.

It is interesting to note that activation of EP₃ receptors evoked diuresis and that EP₃-receptor antagonism was found to induce an antidiuretic effect (Jugus et al, 2009). Thus, to modulate bladder activity, it appears that the EP₃ receptor has a role in regulating urine production. Both effects may be useful for treatment of OAB and DO. It cannot be denied that EP₁ and EP₃ receptors constitute interesting and promising targets for drugs aimed at OAB and DO treatment. However, a randomized, double-blind, placebo-controlled phase II study to investigate the efficacy and safety of the EP₁-receptor antagonist ONO-8539 in patients with the OAB syndrome suggests that the role of EP₁-receptor antagonism in the management of the OAB syndrome is minimal (Chapple et al, 2014a).

Intraprostatically Injected Drugs

NX-1207. NX-1207 is a new drug under investigation for the treatment of LUTS associated with BPH. It is a new therapeutic protein of proprietary composition with selective proapoptotic properties (Shore, 2010). The drug is injected directly into the transitional zone of the prostate as a single administration to induce focal cell loss in prostate tissue through apoptosis, leading to nonregressive prostate shrinkage and both short- and long-term symptomatic improvement. Information about the drug is scarce and mostly published in abstract form and not yet in the peer-reviewed literature. Two U.S. phase II trials have been performed (Shore, 2010). One of them was a multicenter, randomized, noninferiority study involving 32 clinical sites with 85 patients and two dose ranges (2.5 and 0.125 mg) and an active open-label comparator (finasteride). Patients and investigators on NX-1207 were double-blind as to dose. The primary end point was change in American Urological Association (AUA) Symptom Index score at 90 and 180 days for a single injection of NX-1207 as compared with finasteride on a noninferiority basis. Inclusion criteria included an AUA symptom score of 15 or higher, diminished peak urine flow (<15 mL/sec), and a prostate size of 30 to 70 mg. The mean AUA symptom score improvement after 90 days in the intent-to-treat group was 9.71 points for 2.5-mg NX-1207 (n = 48) versus 4.13 points for finasteride (n = 24) (*P* = .001) and 4.29 for 0.125-mg NX-1207 (n = 7) (*P* = .034). The 180-day results also were positive (NX-1207 2.5 mg noninferior to open-label finasteride).

No significant changes in serum testosterone or serum prostate-specific antigen (PSA) levels were noted in the NX-1207 cohorts. There were no reported adverse effects on sexual function. Two U.S. multicenter, double-blind, placebo-controlled phase III studies are currently underway. The results of such studies are needed to assess whether or not this therapeutic principle is a useful addition to the current treatment alternatives.

PRX302. PRX302 is a modified form of proaerolysin, a highly toxic bacterial pore-forming protoxin that requires proteolytic processing by PSA (Singh et al, 2007). The safety and efficacy of PRX302 was

evaluated in men with moderate-to-severe BPH (Denmeade et al, 2011). The patients were refractory, intolerant, or unwilling to undergo medical therapies for BPH and had an IPSS higher than 12, a QoL score higher than 3, and prostate volumes of 30 to 80 g. Fifteen patients were enrolled in phase I studies, and 18 patients entered phase II studies. Patients received intraprostatic injection of PRX302 into the right and left transition zone via a transperineal approach in an office-based setting. Phase I subjects received increasing concentrations of PRX302 at a fixed volume; phase II subjects received increasing volumes per deposit at a fixed concentration. IPSS, QoL, prostate volume, Qmax, IIEF score, serum PSA levels, pharmacokinetics, and adverse events were recorded at 30, 60, 90, 180, 270, and 360 days after treatment. Sixty percent of men in the phase I study and 64% of men in the phase II study treated with PRX302 had greater than 30% improvement compared with baseline in IPSS out to day 360. Patients also experienced improvement in QoL and reduction in prostate volume out to day 360. Patients receiving more than 1 mL of PRX302 per deposit had the best response overall. There were no deleterious effects on erectile function. Adverse events were mild to moderate and transient in nature. The major study limitation was the small sample size.

Elhilali and colleagues (2013) conducted a phase IIb double-blind safety and efficacy evaluation of intraprostatic injection of PRX302 in 92 patients with IPSS of 15 or greater, peak urine flow of 12 mL/sec or less, and prostate volume of 30 to 100 mL. The patients were randomized 2:1 to a single ultrasound-guided intraprostatic injection of PRX302 versus vehicle (placebo). It was concluded that PRX302 produced clinically meaningful and statistically significant improvement in patient subjective (IPSS) and quantitative objective (peak urine flow) measures sustained for 12 months.

Cannabinoids. There is increasing evidence that cannabinoids can influence micturition in animals as well as in humans, both normally and in bladder dysfunction (Ruggieri, 2011). The effects of the cannabinoids are exerted via two types of well defined receptors, CB₁ and CB₂, distributed widely in the body. However, additional receptor subtypes cannot be excluded (Pertwee et al, 2010; Ruggieri, 2011). Both in the CNS and in peripheral tissues, CB₁ and CB₂ receptors have been identified; centrally CB₁ and peripherally CB₂ receptors seem to be predominant (Pertwee et al, 2010; Ruggieri, 2011). CB₁ as well as CB₂ receptors have been identified in all layers of the human bladder (Merriam et al, 2008; Gratzke et al, 2009; Tyagi et al, 2009; Walczak et al, 2009); their expression in the urothelium was found to be significantly higher than in the detrusor, and the expression of CB₁ was higher than that of CB₂ (Tyagi et al, 2009). Gratzke and colleagues (2009) found higher expression of CB₂ receptors, but not CB₁ receptors, in the mucosa than in the detrusor. Compared with the detrusor, larger amounts of CB₂ receptor-containing nerves that also expressed TRPV1 or CGRP were observed in the suburothelium. Nerve fibers containing CB₂ receptors and VACHT (cholinergic neurons) were located in the detrusor. In general, activation of CB₁ peripherally has been associated with vasodilation and motility changes via suppression of release of neurotransmitters, whereas activation of CB₂ appears to induce anti-inflammatory, antinociceptive, and immunosuppressive actions (Pertwee et al, 2010; Ruggieri, 2011). Several animal studies have suggested a modulatory role of CB₂ receptors in both afferent signaling and cholinergic nerve activity (Gratzke et al, 2009, 2010, 2011). Thus, in vivo the selective CB₂-receptor agonist, cannabimimetic, increased micturition intervals and volumes and increased threshold and flow pressures, suggesting that peripheral CB₂ receptors may be involved in sensory functions. In rats with partial urethral obstruction treated daily for 14 days with cannabimimetic, bladder weight was lower, the ability to empty the bladder was preserved, and nonvoiding contraction frequency was low compared with those in controls.

The key enzyme for the degradation of anandamide and other endogenous cannabinoids is fatty acid amide hydrolase (FAAH). FAAH was found to be expressed in rat and human urothelium and was coexpressed with CB₂ receptors. In rats, an FAAH inhibitor altered urodynamic parameters that reflect sensory functions, suggesting a role for the endocannabinoid system in bladder mechanosensory functions (Strittmatter et al, 2012).

It has not been established whether the effects of the cannabinoids are exerted in the CNS (brain, spinal cord) or peripherally. In a preliminary report, [Blyweert and colleagues \(2003\)](#) demonstrated an effect of combined CB₁/CB₂-receptor activation on DO in rats with spinal cord transection, which seemed to exclude the brain as a main site of action.

Clinical experiences with the cannabinoid treatment of micturition disturbances including LUTS are limited ([Ruggieri, 2011](#)), but both open-label and placebo-controlled studies have demonstrated that orally administered cannabinoid modulators may alleviate neurogenic OAB symptoms refractory to first-line treatment ([Brady et al, 2004b](#); [Freeman et al, 2006](#); [Kavia et al, 2010](#)). [Brady and colleagues \(2004b\)](#) evaluated the efficacy of two whole-plant extracts (Δ^9 -tetrahydrocannabinol and cannabidiol) of *Cannabis sativa* in patients with advanced MS and refractory LUTS. Urinary urgency, the number and volume of incontinence episodes, frequency, and nocturia decreased significantly after treatment. [Freeman and colleagues \(2006\)](#) tested in a subanalysis of a multicenter trial (the Cannabinoids in Multiple Sclerosis [CAMS] study) whether cannabinoids could decrease urge incontinence episodes without affecting voiding in patients with MS. The CAMS study randomized 630 patients to receive oral administration of the cannabis extract Δ^9 -tetrahydrocannabinol or matched placebo. Based on incontinence diaries, a significant decrease in incontinence episodes was demonstrated.

[Kavia and colleagues \(2010\)](#) assessed the efficacy, tolerability, and safety of Sativex (nabiximols) as an add-on therapy in alleviating bladder symptoms in patients with MS. They performed a 10-week, double-blind, randomized, placebo-controlled, parallel-group trial on 135 randomized subjects with MS and OAB. The primary end point, reduction in daily number of UI episodes from baseline to end of treatment (8 weeks), showed little difference between Sativex and placebo. However, four of seven secondary end points were significantly in favor of Sativex, including number of episodes of nocturia, number of voids per day, and number of daytime voids. The improvement in I-QoL was in favor of Sativex but did not reach statistical significance.

Systemic cannabinoids have effects on the LUT that may have therapeutic potential; local delivery (intravesical, spinal) may be possible, but more information is needed. The mechanisms of cannabinoid receptors in control of the human LUT are incompletely known, and further research is necessary for the development of novel cannabinoid drugs for treatment of LUT disorders.

Centrally Acting Drugs. Many parts of the brain seem to be activated during storage and voiding ([Griffiths, 2007](#); [Fowler et al, 2008](#); [Griffiths and Tadic, 2008](#); [Griffiths, 2011](#)), and there is increasing interest in drugs modulating the micturition reflex by a central action ([Andersson and Pehrson, 2003](#)). Several drugs used for pain treatment also affect micturition, morphine and some antiepileptic drugs being a few examples. However, central nervous mechanisms have so far not been preferred targets for drugs aimed to treat OAB, because selective actions may be difficult to achieve. [Holstege \(2005\)](#), reviewing some of the central mechanisms involved in micturition, including the periaqueductal gray (PAG) and the pontine micturition center (PMC), suggested that “the problem in OAB or urgency-incontinence is at the level of the PAG or PMC and their connections, and possible treatments for this condition should target the micturition pathways at that level.”

Gonadotropin-Releasing Hormone Antagonists. The beneficial effects of the 5 α -reductase inhibitors finasteride and dutasteride in the treatment of male LUTS are well documented. The efficacy of other hormonal treatments—for example, antiandrogens or gonadotropin-releasing hormone (GnRH; also known as luteinizing hormone-releasing hormone [LHRH]) agonists—is either poor or occurs at the expense of unacceptable side effects such as medical castration associated with hot flashes, decrease of potency and libido, and negative effects on bone density after long-term androgen ablation ([Schroeder et al, 1986](#); [Peters and Walsh, 1987](#); [Bosch et al, 1989](#); [Eri and Tveter, 1993](#)). With GnRH antagonists, submaximal noncastrating blockade of the androgen testosterone and consequently of dihydrotestosterone (DHT) can be achieved, thus

avoiding medical castration. Several GnRH antagonists, such as cetrorelix, ozarelix, and teverelix, have been tested in phase IIA/IIB clinical trials for their ability to improve LUTS in patients with BPH ([Colli and Tankó, 2010](#)).

[Debruyne and colleagues \(2008\)](#) demonstrated in a phase II RCT that the LHRH antagonist cetrorelix, given subcutaneously weekly for 20 weeks to 140 men with LUTS (IPSS ≥ 13 , peak urinary flow rates 5 to 13 mL/sec), rapidly caused a significant improvement in the mean IPSS. The peak decrease was -5.4 to -5.9 versus -2.8 for placebo. All dosage regimens tested were well tolerated, and the authors concluded that the drug offered a safe and effective treatment for male LUTS.

Because of these results, two phase III studies were conducted in the United States and Europe (\AA terna Zentaris); in the U.S. study, 637 men were randomized to receive either two doses of placebo or cetrorelix on weeks 2 and 26. The drug showed no statistically significant benefit in improving IPSS. In addition, cetrorelix did not have a significant effect on peak flow rate or prostate volume versus placebo. It is difficult to reconcile this lack of efficacy, given favorable prior results. A subsequent multicenter European trial also failed to show any treatment-related efficacy of cetrorelix. The experience with cetrorelix highlights the importance of randomized, placebo-controlled trials that are appropriately powered to show clinical benefit and safety.

Gabapentin. Gabapentin is one of the new first-generation antiepileptic drugs that expanded its use into a broad range of neurologic and psychiatric disorders ([Striano and Striano, 2008](#)). It was originally designed as an anticonvulsant GABA mimetic capable of crossing the blood-brain barrier ([Maneuf et al, 2003](#)). The effects of gabapentin, however, do not appear to be mediated through interaction with GABA receptors, and its mechanism of action remains controversial ([Maneuf et al, 2003](#)). It has been suggested that it acts by binding to a subunit of the $\alpha_2\delta$ unit of voltage-dependent calcium channels ([Gee et al, 1996](#); [Striano and Striano, 2008](#)). Gabapentin is also widely used not only for seizures and neuropathic pain, but for many other indications, such as anxiety and sleep disorders, because of its apparent lack of toxicity.

[Carbone and colleagues \(2006\)](#) reported on the effect of gabapentin on NDO. They found a positive effect on symptoms and significant improvement in urodynamic parameters and suggested that the effects of the drug should be explored in further controlled studies in both NDO and non-neurogenic DO. [Kim and colleagues \(2004\)](#) studied the effects of gabapentin in patients with OAB and nocturia not responding to antimuscarinics. They found that 14 of 31 patients improved with oral gabapentin. The drug was generally well tolerated, and the authors suggested that it can be considered in selective patients when conventional modalities have failed. It is possible that gabapentin and other α,δ ligands (e.g., pregabalin and analogues) will offer new therapeutic alternatives, but convincing RCTs are still lacking.

Tramadol. Tramadol is a well-known analgesic drug ([Grond and Sablotzski, 2004](#)). By itself, it is a weak μ -receptor agonist, but it is metabolized to several different compounds, some of them almost as effective as morphine at the μ receptor. However, the drug (metabolites) also inhibits serotonin (5-HT) and NA reuptake ([Grond and Sablotzski, 2004](#)). This profile is of particular interest, because both μ -receptor agonism and amine reuptake inhibition may be useful principles for treatment of LUTS, OAB, and DO, as shown in a placebo-controlled study with duloxetine ([Steers et al, 2007](#)).

In rats, tramadol abolished experimentally induced DO caused by cerebral infarction ([Pehrson and Andersson, 2003](#)). Tramadol also inhibited DO induced by apomorphine in rats ([Pehrson and Andersson, 2003](#))—a crude model of bladder dysfunction in Parkinson disease. [Singh and colleagues \(2008\)](#) gave tramadol epidurally and found the drug to increase bladder capacity and compliance and to delay filling sensations without adverse effects on voiding. [Safarinejad and Hosseini \(2006\)](#) evaluated in a double-blind, placebo-controlled, randomized study the efficacy and safety of tramadol in patients with IDO. A total of 76 patients 18 years or older were given 100 mg of tramadol SR every 12 hours for 12

weeks. Clinical evaluation was performed at baseline and every 2 weeks during treatment. Tramadol significantly ($P < .01$) reduced the number of incontinence periods per 24 hours from 3.2 ± 3.3 to 1.6 ± 2.8) and induced improvements in urodynamic parameters. The main adverse event was nausea. It was concluded that in patients with non-neurogenic DO, tramadol provided beneficial clinical and urodynamic effects. Even if tramadol may not be the most suitable drug for treatment of LUTS and OAB, the study suggests efficacy for modulation of micturition via the μ receptor.

NK1-Receptor Antagonists. The main endogenous tachykinins—SP, neurokinin A (NKA), and neurokinin B (NKB)—and their preferred receptors—NK₁, NK₂, and NK₃, respectively—have been demonstrated in various CNS regions, including those involved in micturition control (Lecci and Maggi, 2001; Covenas et al, 2003; Saffroy et al, 2003). NK₁ receptor-expressing neurons in the dorsal horn of the spinal cord may play an important role in DO, and tachykinin involvement via NK₁ receptors in the micturition reflex induced by bladder filling has been demonstrated (Ishizuka et al, 1994) in normal rats and, more clearly, rats with bladder hypertrophy secondary to BOO. Capsaicin-induced DO was reduced by blocking NK₁ receptor-expressing neurons in the spinal cord, using intrathecally administered SP-saponin conjugate (Seki et al, 2005). Furthermore, blockade of spinal NK₁ receptor could suppress detrusor activity induced by dopamine receptor (L-dopa) stimulation (Ishizuka et al, 1995).

In conscious rats undergoing continuous cystometry, antagonists of both NK₁ and NK₂ receptors inhibited micturition, decreasing micturition pressure and increasing bladder capacity at low doses and inducing dribbling incontinence at high doses. This was most conspicuous in animals with outflow obstruction (Gu et al, 2004). Intracerebroventricular administration of NK₁- and NK₂-receptor antagonists to awake rats suppressed detrusor activity induced by dopamine receptor (L-dopa) stimulation (Ishizuka et al, 2000). Taken together, available information suggests that spinal and supraspinal NK₁ and NK₂ receptors may be involved in micturition control.

Aprepitant, an NK₁-receptor antagonist used for treatment of chemotherapy-induced nausea and vomiting (Massaro and Lenz, 2005), significantly improved symptoms of OAB in postmenopausal women with a history of urgency incontinence or mixed incontinence (with predominantly UII), as shown in a well-designed pilot RCT (Green et al, 2006). The primary end point was percent change from baseline in average daily micturitions assessed by a voiding diary. Secondary end points included average daily total UI and urgency incontinence episodes and urgency episodes. Aprepitant significantly ($P < .003$) decreased the average daily number of micturitions (-1.3 ± 1.9) compared with placebo (-0.4 ± 1.7) at 8 weeks. The average daily number of urgency episodes was also significantly ($P < .047$) reduced ($-23.2 \pm 32\%$) compared with placebo ($-9.3 \pm 40\%$), and so were the average daily number of urgency incontinence and total UI episodes, although the difference was not statistically significant. In general, aprepitant was well

tolerated and the incidence of side effects, including dry mouth, was low.

Since this initial proof-of-concept study suggested that NK₁-receptor antagonism holds promise as a potential treatment approach for OAB symptoms, a randomized, double-blind, multicenter trial enrolled 557 adults with OAB (eight or more average daily micturitions and one or more daily urge incontinence episodes) (Frenkl et al, 2010). After a 1-week placebo run-in, the patients were randomized to treatment with 8 weeks of daily 0.25-, 1-, or 4-mg serlopitant; 4-mg tolterodine ER; or placebo. Patients kept 7-day voiding diaries. The primary end point was change from baseline in micturitions per day. Secondary end points included urgency, total incontinence, urge incontinence episodes, and incidence of dry mouth. Of the 557 patients randomized, 476 completed the trial and had valid efficacy data for analysis. Mean change from baseline in daily micturitions was significantly greater for 0.25-mg (-1.1) and 4-mg (-1.1) serlopitant and for tolterodine (-1.5) than for placebo (-0.5), but not for 1-mg serlopitant (-0.8). No serlopitant dose response was demonstrated. Tolterodine was numerically superior to all doses of serlopitant in mean micturitions per day and secondary end points. The incidence of dry mouth on serlopitant (3.3%) was comparable to that on placebo (4.6%) and lower than tolterodine (8.8%). Serlopitant was generally well tolerated.

NK₁-receptor antagonists may have a role in the treatment of OAB, but at least the compounds tested so far do not offer advantages in efficacy compared with tolterodine.

A different approach, modulation of neuropeptide release rather than NK-receptor blockade, was tested in a pilot study with cizolirtine, which is an SP and CGRP release modulator at the spinal cord level. The modulation of SP and CGRP is probably related to the increase in extracellular levels of NA and serotonin. Cizolirtine 200 and 400 mg were compared with placebo in 79 OAB patients. Although the decrease in key OAB symptoms was significantly higher in the active arms, adverse events were reported in 68% and 81% of the patients on cizolirtine 200 and 400 mg. More commonly reported side effects were gastrointestinal in nature, including dry mouth and dizziness (Martínez-García et al, 2009).

KEY POINTS: OVERACTIVE BLADDER MECHANISMS AND TARGETS

- There are a number of possibilities, mostly based on theoretic mechanisms of action and studies in experimental animals, for drugs to favorably affect the symptoms of OAB and NDO or IDO.
- These mechanisms, at both the central and the peripheral levels, are intriguing, but with the possible exception of drugs directed at prostate bulk or internal organization, none have achieved consistent clinical success.

Estrogens for Stress Urinary Incontinence. The role of estrogen in the treatment of SUI has been controversial despite a number of reported clinical trials (Hextall, 2000). Some have given promising results, but this may have been because they were small observational studies and not randomized, blinded, or controlled. The situation is further complicated by the fact that a number of different types of estrogen have been used with varying doses, routes of administration, and durations of treatment.

Fantl and colleagues (1996) treated 83 hypoestrogenic women with urodynamic stress incontinence and/or DO with CEEs 0.625 mg and medroxyprogesterone 10 mg cyclically for 3 months. Controls received placebo tablets. At the end of the study period the clinical and QoL variables had not changed significantly in either group. Jackson and colleagues (1996) treated 57 postmenopausal women with urodynamic stress or mixed incontinence with estradiol 2 mg or placebo daily for 6 months. There was no significant change in objective outcome measures, although both the active and placebo groups reported subjective benefit.

Two meta-analyses of early data have been performed. In the first, a report by the Hormones and Urogenital Therapy (HUT) Committee, the use of estrogens to treat all causes of incontinence in postmenopausal women was examined (Fantl et al, 1994). Of 166 articles identified, which were published in English from 1969 to 1992, only 6 were controlled trials and 17 were uncontrolled series. The results showed that there was a significant subjective improvement for all patients and those with urodynamic stress incontinence. However, assessment of the objective parameters revealed that there was no change in the volume of urine lost; maximum urethral closure pressure increased significantly, but this result was influenced by only one study showing a large effect.

In the second meta-analysis, Sultana and Walters (1990) reviewed 8 controlled and 14 uncontrolled prospective trials and included all types of estrogen treatment. They also found that estrogen therapy was not an efficacious treatment for SUI but may be useful for the often associated symptoms of urgency and frequency. Estrogen when given alone therefore does not appear to be an effective treatment for SUI.

Several studies have shown that estrogen may have a role in combination with other therapies—for example, α -adrenoceptor agonists. However, phenylpropanolamine (the most widely used α -adrenoceptor agonist in clinical practice) has now been restricted or banned by the FDA.

In a randomized trial, Ishiko and colleagues (2001) compared the effects of the combination of pelvic floor exercise (PFE) and estriol (1 mg/day) in 66 patients with postmenopausal SUI. Efficacy was evaluated every 3 months based on stress scores obtained from a questionnaire. They found a significant decrease in stress score in mild and moderate stress-incontinent patients in both groups 3 months after the start of therapy and concluded that combination therapy with estriol plus PFE was effective and could be used as first-line treatment for mild SUI. Unfortunately, this has not been reproduced in other clinical trials.

Thus, even before the more recently reported secondary analyses of HERS (Grady et al, 2001) and WHI (Hendrix et al, 2005), it was already recognized that estrogen therapy had little effect in the management of urodynamic stress incontinence (Al-Badr et al, 2003; Robinson and Cardozo, 2003).

α -Adrenoceptor agonists. Several drugs with agonistic effects on peripheral α -ARs have been used in the treatment of SUI. Relatively recently, a central role of NA has been discovered in increasing the excitability of urethral rhabdosphincter motoneurons in the rat analog of the Onuf nucleus, an effect caused at least in part by α_1 -AR-dependent depolarization. This could contribute to the mechanism by which NA reuptake inhibitors improve SUI (Yashiro et al, 2010). Ephedrine and norephedrine (phenylpropanolamine [PPA]) seem to have been the most widely used (Andersson and Wein, 2012). The original AHCPR guidelines (AHCPR, 1992) reported eight RCTs with PPA, 50 mg twice daily for SUI in women. Percent cures (all figures refer to percent effect in patients on drug minus percent effect in patients on placebo) were listed as 0% to

14%; percent reduction in continence as 19% to 60%; and percent side effects and percent dropouts as 5% to 33% and 0% to 4.3%, respectively. The most recent Cochrane review on the subject (Alhasso et al, 2005, reprinted virtually unchanged in 2008) assessed randomized or quasi-randomized controlled trials in adults with SUI that included an adrenergic agonist drug in at least one arm of the trial. There were no controlled studies reported on the use of such drugs in men. Twenty-two eligible trials were identified, 11 of which were crossover trials, which included 1099 women, 673 of whom received an adrenergic drug (PPA in 11, midrodrine in 2, norepinephrine in 3, clenbuterol in 3, terbutaline in 1, eskornade in 1, and RO 115-1240 in 1). The authors concluded that “there was weak evidence to suggest that use of an adrenergic agonist was better than placebo in reducing the number of pad changes and incontinence episodes, as well as improving subjective symptoms.” There was not enough evidence to evaluate the merits of an adrenergic agonist compared with estrogen, whether used alone or in combination. Regarding adverse events, the review reported similar numbers with adrenergic, placebo, or alternative drug treatment. Over 25% of subjects reported such effects, but when these consisted of effects resulting from adrenergic stimulation, they caused discontinuation in only 4% of the total.

Ephedrine and PPA lack selectivity for urethral α -ARs and can increase blood pressure and cause sleep disturbances, headache, tremor, and palpitations (Andersson and Wein, 2012). Kernan and colleagues (2000) reported the risk of hemorrhagic stroke to be 16 times higher in women younger than 50 years who had been taking PPA as an appetite suppressant (statistically significant) and 3 times higher in women who had been taking the drug for less than 24 hours as a cold remedy (not statistically significant). There was no increased risk in men. PPA has been removed from the market in the United States. It is still allowed as a treatment for SUI in a few countries. Numerous case reports of adverse reactions caused by ephedra alkaloids exist, and some (Bent et al, 2003) suggested that sale of these compounds as a dietary supplement be restricted or banned. In December 2003, the FDA decreed such a ban, a move which has survived legal appeal.

Midrodrine and methoxamine stimulate α_1 -ARs with some degree of selectivity. According to the RCTs available, the effectiveness of these drugs is moderate at best, and the clinical usefulness seems to be limited by adverse effects (Weil et al, 1998; Radley et al, 2001; Alhasso et al, 2003).

Attempts to develop agonists with relative selectivity for the human urethra continue. Musselman and colleagues (2004) reported on a phase II randomized crossover study with Ro 115-1240, a peripherally active selective $\alpha_{1A/1L}$ -AR partial agonist (Blue et al, 2004), in 37 women with mild-to-moderate SUI. A moderate, positive effect was demonstrated, but side effects have apparently curtailed further development of the drug. PF-3774076, a CNS-penetrating partial α_{1A} -AR agonist, increased peak urethral pressure in dogs and was selective with respect to α_{1B} and α_{1D} receptors, but HR and blood pressure changes caused significant concern (Conlon et al, 2009). Furuta and colleagues (2009) reported that the α_2 -AR can inhibit the release of glutamate presynaptically in the spinal cord and proposed that α_2 -AR antagonists would be useful as a treatment for SUI. This hypothesis awaits testing.

β -Adrenoceptor Agonists

Clenbuterol. β -AR stimulation is generally conceded to decrease urethral pressure (Andersson, 1993), but β_2 -AR agonists have been reported to increase the contractility of some fast-contracting striated muscle fibers and suppress that of slow-contracting fibers of others (Fellenius et al, 1980). Some β -AR agonists also stimulate skeletal muscle hypertrophy—in fast-twitch more than slow-twitch fibers (Kim and Sainz, 1992). Clenbuterol has been reported to potentiate the field stimulation-induced contraction in rabbit isolated periurethral muscle preparations, an action that is suppressed by propranolol and greater than that produced by isoproterenol (Kishimoto et al, 1991). These authors were the first to report an increase in urethral pressure with clinical use of clenbuterol and to speculate on its potential for the treatment of SUI. Yamanishi and colleagues (1994) reported an inotropic effect of clenbuterol and

terbutaline on the fatigued striated urethral sphincter of dogs, abolished by β -AR blockade.

Yasuda and colleagues (1993) described the results of a double-blind placebo-controlled trial with this agent in 165 women with SUI. Positive statistical significance was achieved for subjective evaluation of incontinence frequency, pad use per day, and overall global assessment. Pad weight decreased from 11.7 ± 17.9 g to 6.0 ± 12.3 g for drug and from 18.3 ± 29.0 g to 12.6 ± 24.7 g for placebo, raising questions about the comparability of the two groups. The "significant" increase in maximal urethral closure pressure (MUCP) was from 46.0 ± 18.2 cm H₂O to 49.3 ± 19.1 cm H₂O, versus a change of -1.5 cm H₂O in the placebo group. Fifty-six of 77 patients in the clenbuterol group reported some degree of improvement versus 48 of 88 in the placebo group. The positive effects were suggested to be a result of an action on urethral striated muscle and/or the pelvic floor muscles. Ishiko and colleagues (2000) investigated the effects of clenbuterol on 61 female patients with stress incontinence in a 12-week randomized study, comparing drug therapy and PFEs. The frequency and volume of stress incontinence and the patient's own impression were used as the basis for the assessment of efficacy. The improvement in incontinence was 76.9%, 52.6%, and 89.5% in the respective groups. In an open study, Noguchi and colleagues (1997) reported positive results with clenbuterol (20 mg bid for 1 month) in 9 of 14 patients with mild-to-moderate stress incontinence after radical prostatectomy (RP). Further well-designed RCTs investigating effects of clenbuterol are needed to adequately assess its potential as a treatment for stress incontinence.

β -Adrenoceptor Antagonists. The theoretic basis for the use of β -AR antagonists in the treatment of stress incontinence is that blockade of urethral β -ARs may enhance the effects of NA on urethral α -ARs. Propranolol has been reported to have beneficial effects in the treatment of stress incontinence (Gleason et al, 1974; Kaisary, 1984), but there are no RCTs supporting such an action. In the study by Gleason and colleagues (1974), the beneficial effects manifest only after 4 to 10 weeks of treatment, a phenomenon that is difficult to explain. Donker and Van der Sluis (1976) reported that β -blockade did not change urethral pressure profile in normal women. Although suggested as an alternative to α -AR agonists in patients with SUI and hypertension, these agents may have major potential cardiac and pulmonary side effects of their own, related to their therapeutic β -AR blockade.

Serotonin-Noradrenaline Uptake Inhibitors

Imipramine. Imipramine, among several other pharmacologic effects, has classically been reported to inhibit the reuptake of NA and serotonin in adrenergic nerve endings. In the urethra this could theoretically be expected to enhance the contractile effects of NA on urethral smooth muscle by both a peripheral and a central action. Gilja and colleagues (1984) reported in an open study on 30 women with stress incontinence that imipramine, 75 mg daily, produced subjective continence in 21 patients and increased mean MUCP from 34 to 48 mm Hg. A 35% cure rate was reported by pad test and, in an additional 25%, a 50% or more improvement. Lin and colleagues (1999) assessed the efficacy of imipramine (25 mg of imipramine three times a day for 3 months) as a treatment for genuine stress incontinence in 40 women with genuine stress incontinence. A 20-minute pad test, uroflowmetry, filling and voiding cystometry, and stress urethral pressure profile were performed before and after treatment. The efficacy of "successful treatment" was 60% (95% CI 11.8 to 75.2). There are no RCTs on the effects of imipramine on SUI. No subsequent published reports have appeared.

It is interesting to note that Gillman (2007) reported that clomipramine had far greater 5-HT reuptake inhibition than imipramine and roughly similar NA reuptake inhibition. Desipramine and reboxetine had greater NA reuptake inhibition (desipramine superior), with lesser effect than imipramine on 5-HT uptake (desipramine superior).

Duloxetine. Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor that has been shown to significantly increase sphincteric muscle activity during the filling

and storage phase of micturition in the cat acetic acid model of irritated bladder function (Thor and Katofiasc, 1995; Katofiasc et al, 2002). Bladder capacity was also increased in this model, with both effects mediated centrally through both motor efferent and sensory afferent modulation (Fraser et al, 2003). The sphincteric effects were reversed by α_1 -adrenergic antagonism (prazosin) and 5-HT₂ serotonergic antagonism (LY-53857), whereas the bladder effects were mediated by temporal prolongation of the actions of serotonin and norepinephrine in the synaptic cleft (Fraser et al, 2003). Duloxetine is lipophilic, well absorbed, and extensively metabolized (CYP2D6). Its plasma half-life is approximately 12 hours (Sharma et al, 2000).

Thor and colleagues (2007) described the mechanisms of action and the physiologic effects of duloxetine. 5-HT (serotonin) and NA terminals are dense in spinal areas associated with LUT functioning, especially around the pudendal nerve neurons in the Onuf nucleus. These are projections from separate areas in the brainstem. Glutamate is the primary excitatory neurotransmitter in the spinal cord, activating the pudendal neurons in the Onuf nucleus, causing contraction of the urethral rhabdosphincter. The rhabdosphincter innervation is proposed as distinct from that of the levator ani (Thor and de Groat, 2010). The responsiveness of the rhabdosphincter motor neurons to glutamate is modulated (facilitated) by 5-HT (through 5-HT₂ receptors) and NA (through α_1 -ARs). 5-HT and NA, however, only modulate, and, when micturition occurs, glutamate excitation and rhabdosphincter contraction cease. Excitatory effects on urethral sphincter activity are shared to a lesser extent by receptors for 5-HT_{1A} (indirect through a supraspinal stimulation), thyrotropin-releasing hormone vasopressin, *N*-methyl-D-aspartate (NMDA), and AMPA; inhibitory effects are similarly mediated by κ_2 opioid receptors, α_1 -ARs, and GABA-A, GABA-B, and glycine receptors (Thor and de Groat, 2010). Some CNS-penetrant selective 5-HT_{2C} agonists have been found to increase urethral muscle tone and inhibit micturition reflexes in animal models, and these are additional candidates for clinical development for the treatment of SUI (Brennan et al, 2009; Andrews et al, 2011).

Several RCTs have documented the effect of duloxetine in SUI (Norton et al, 2002; Dmochowski et al, 2003a; Millard and the Asia Pacific Tolterodine Study Group, 2004; Van Kerrebroeck et al, 2004). A Cochrane review of the effects of duloxetine for SUI in women is available; the last substantive amendment is listed as May 25, 2005 (Mariappan et al, 2005). Fifteen reports were deemed eligible for analysis, 9 primary studies and 6 additional reports related to 1 or 2 of the primary references. An additional analysis "performed under the auspices of the Cochrane Incontinence Group" was performed on just the 9 primary trials comparing duloxetine and placebo, and published separately (Mariappan et al, 2005). The results can be summarized as follows. Subjective "cure" in the duloxetine 80 mg daily (40 mg bid) group was higher than in the placebo group (10.8% vs. 7.7%, overall relative risk [RR] 1.42, 95% CI 1.02 to 1.98, $P = .04$). The estimated absolute size of effect was about 3 more patients cured for every 100 treated. Objective cure data, available from only 1 trial, showed no clear difference between drug and placebo. Duloxetine showed greater improvement in I-QoL (weighted mean difference for 80 mg 4.5, 95% CI 2.83 to 6.18, $P < .00001$). Adverse effects in 6 trials were analyzed. These were reported by 71% of drug subjects and 59% of those allocated to placebo. Nausea was the most common adverse event, with an incidence that ranged from 23% to 25%, and was the main reason for discontinuation. Other side effects reported were vomiting, constipation, dry mouth, fatigue, dizziness, and insomnia—overall RR was 1.30 (95% CI 1.23 to 1.37). Across these 6 trials, 17% in the drug group withdrew, as did 4% in the placebo arm. In the 2007 article, the authors conclude by saying that further research is needed regarding whether management policies incorporating duloxetine are clinically effective and cost-effective compared with other current minimally invasive and more invasive approaches in patients with varying severity of SUI, and that "longer term experience is now a priority to determine whether there is sustained efficacy during and after duloxetine use and to rule out complications."

Hurley and colleagues (2006) characterized the safety of duloxetine for treatment of SUI in women, using an integrated database

generated from four published placebo-controlled clinical trials. The database included 1913 women randomized to duloxetine (958) or placebo (955), examining adverse events, serious adverse events, vital signs, ECGs, and laboratory analytes. Adverse events occurring initially or worsening during the double-blind treatment period were considered treatment emergent. Differences between duloxetine-treated and placebo-treated groups were compared statistically. Common treatment-emergent adverse events included nausea (23.2%), dry mouth (13.4%), fatigue (12.7%), insomnia (12.6%), constipation (11.0%), headache (9.7%), dizziness (9.5%), somnolence (6.8%), and diarrhea (5.1%). Most treatment-emergent adverse events that emerged early were mild to moderate, rarely worsened, and resolved quickly. Overall, adverse event discontinuation rates were 20.5% for duloxetine and 3.9% for placebo ($P < .001$). Most discontinuations (83%) occurred within the first month of treatment. Serious adverse events were uncommon and did not differ between treatments. Statistically significant but clinically unimportant mean increases in HR (2.4 beats/min) and systolic and diastolic blood pressure (≤ 2 mm Hg) occurred. No arrhythmogenic potential was observed, and any rare, transient, asymptomatic increases in hepatocellular enzymes were normalized. The authors concluded that duloxetine was safe and tolerable, although transient adverse events were not uncommon. Hashim and Abrams (2006) suggested that to reduce the risk of nausea, treatment should begin with a dose of 20 mg twice daily for 2 weeks, which should then be increased to the recommended 40-mg bid dose.

Ghoneim and colleagues (2005) randomized women with SUI to one of four treatment combinations: duloxetine alone (40 mg bid), pelvic floor muscle training (PFMT), combination, and placebo. Overall, drug with or without PFMT was superior to PFMT alone or placebo, whereas pad results and QoL data favored combination therapy over single treatment. Cardozo and colleagues (2004a) reported that 20% of women awaiting continence surgery changed their minds while taking duloxetine. Duckett and colleagues (2006) offered a 4-week course to women awaiting a tension-free vaginal tape operation. Thirty-seven percent (of 73) declined. Excluding women for whom concomitant prolapse surgery was planned, 8 of 33 (24%) scheduled for incontinence surgery alone came off the list. Sixteen (48%) discontinued duloxetine because of adverse events, and 9 (27%) found the drug ineffective.

Bent and colleagues (2008) reported on the effects of 12 weeks of duloxetine (40 mg bid) versus placebo in a large group of women with mixed urinary incontinence (MUI). For SUI episodes, the mean IEF per week decreased 58.9% with drug (7.69 to 3.93) versus 43.3% for placebo (8.93 to 6.05). It is interesting to note that corresponding decreases for UUI episodes were 57.7% versus 39.6%. Both sets of values are statistically significant, but the baselines are different and the absolute change for SUI amounted to -3.76 episodes per week for drug and -2.87 for placebo. Nausea was reported by 18% of patients on drug and 4.5% on placebo. Corresponding percents for other adverse events included dry mouth (12 vs. 2.8), dizziness (9.7 vs. 2.4), constipation (8.3 vs. 4.2), and fatigue (6.7 vs. 2.8). Nausea and dizziness were less common in a subgroup taking concurrent antidepressants. Women 65 years and older with SUI or stress-predominant MUI (S-MUI) were given duloxetine (40 mg bid after a 2-week start on 20 mg bid) or placebo for 12 weeks by Schagen van Leeuwen and colleagues (2008). Their report concludes that "this study supports the use of duloxetine in elderly women with SUI or S-MUI." The data show an absolute change in SUI plus S-MUI episodes of -11.7 and -6.9 incontinence per week (drug and placebo) and median percent changes of -52.5% versus -36.7% from 24-hour diaries, both significant at $P < .001$. However, the changes for SUI alone were -53% versus -42% (nonsignificant), whereas for S-MUI alone they were -51.6% versus -32.7% ($P < .001$). Nausea was less than in other trials (7.5% vs. 3.1%), perhaps because of the lower starting dose. Other adverse events included fatigue (14.2% vs. 5.4%), constipation (10.4% vs. 0.8%), dizziness (9.0% vs. 4.6%), and excess sweating (5.2% vs. 0%).

Persistence on duloxetine was studied by Vella and colleagues (2008), who found that only 31% of an original cohort of 228 were

still taking drug beyond 4 weeks, 12% at 4 months, 10% at 6 months, and 9% at 1 year. Fifty-six percent of the discontinuations were attributed to side effects, and 33% to lack of efficacy. Bump and colleagues (2008), however, reported that the positive effects of duloxetine were maintained in patients who continued treatment up to 30 months, but admitted that this subgroup was likely to include predominantly patients who had favorable responses. The number decreased from 1424 in this cohort at 3 months to 368 at 30 months.

Shaban and colleagues (2010) concluded that duloxetine is "optional second line for women not willing or unfit for surgery after warning against side effects as recommended by NICE [National Institute for Health and Care Excellence] guidelines in the UK." Similar sentiments have been expressed by Robinson and Cardozo (2010).

Duloxetine is licensed at 40 mg twice daily for the treatment of SUI in the European Union in women with moderate-to-severe incontinence (defined as 15 or more episodes per week). It was withdrawn from the FDA consideration process in the United States for the treatment of SUI but is approved for the treatment of major depressive disorder (20 to 30 mg bid initially, 60 mg once daily for maintenance), diabetic peripheral neuropathic pain (60 mg once daily), generalized anxiety disorder (60 mg once daily), fibromyalgia (30 mg once daily initially, 60 mg once daily for maintenance), and chronic musculoskeletal pain (30 mg once daily initially, 60 mg once daily for maintenance). The product information contains a black box warning of "increased risk of suicidal thinking and behavior in children, adolescents and young adults taking antidepressants for major depressive disorder and other psychiatric disorders," noting also that "depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide" (Cymbalta prescribing information, revised September 2011). Other warnings and precautions in the prescribing information for psychiatric indications, not SUI, include hepatotoxicity (not to be used in patients with substantial alcohol use or chronic liver disease); orthostatic hypotension; serotonin syndrome (general statement regarding SSRIs and SNRIs); abrupt discontinuation (may result in dizziness, paresthesias, irritability, and headache); inhibitors of CYP1A2 (such as ciprofloxacin) and thioridazine (do not administer concomitantly); and potent inhibitors of CYP2D6 (may increase concentration). Adverse events for 6801 drug- and 4487 placebo-treated patients reported in the prescribing information for Cymbalta (treatment for the indications mentioned) are nausea (24% vs. 8%), dry mouth (13% vs. 5%), fatigue (10% vs. 5%), somnolence (10% vs. 3%), insomnia (10% vs. 6%), constipation (10% vs. 4%), and dizziness (10% vs. 5%).

Stress Urinary Incontinence in Men

Although a problem of significant magnitude, especially after RP for cancer, the pharmacologic treatment of male SUI is an area that has received relatively little attention.

Intrinsic sphincter function is the most important outlet factor maintaining continence in men. Urethral support is less important, and there is no entity similar to the hypermobility phenomenon in women. The proximal urethral sphincter extends from the bladder neck through the prostatic urethra. Its function is removed by RP. The distal urethral sphincter includes the rhabdosphincter, urethral smooth muscle, and extrinsic paraurethral skeletal muscle, extending from the prostatic urethra below the verumontanum through the membranous urethra (Koelbl et al, 2009). Tsakiris and colleagues (2008) searched for articles on drug treatment of male SUI published from 1966 to June 2007 and did a generalized database search in addition. Nine trials were identified as using α -adrenergic agonists, β_2 antagonists, or SNRIs. Only one of these included a comparison arm (Filocamo et al, 2007), 40-mg bid duloxetine plus PFE versus PFE with placebo. The results suggested a positive effect of drug but were a bit confusing. Of patients completing the 4-month trial (92 of 112) 78% of the drug-treated patients versus 52% of those in the placebo group were "dry." However, 1 month after the end of the study, the corresponding figures were 46%

versus 73%, a shift still observed 2 months later. The authors of the review article recommended further larger and well-designed studies on duloxetine for this potential use.

Cornu and colleagues (2011) reported a series of post-RP men with SUI or S-MUI randomized to duloxetine (15) and placebo (16) after a 2-week placebo run-in. Dosage was 20 mg bid for 7 days, 40 mg bid for 67 days, and 20 mg for 14 days. Subjects were at least 1 year postsurgery. Outcome measures included percent decrease in IEF, 1-hour pad test, and various QoL measures. Statistical significance for IEF percent decrease occurred only at weeks 8 and 12 ($[-]52.2\% \pm 38.6\%$ vs. $[+]19\% \pm 43.5\%$), but there was clearly a trend at 4 weeks. There was no statistical difference in 1-hour pad test weights, but there was in various QoL scores. A 50% to 100% decrease in IEF was seen at 12 weeks in over half the patients. Adverse events for drug and placebo included fatigue (50% vs. 13%), insomnia (25% vs. 7%), libido loss (19% vs. 7%), constipation (13% vs. 7%), nausea (13% vs. 7%), diarrhea (13% vs. 7%), dry mouth (6% vs. 0%), anorexia (6% vs. 0%), and sweating (25% vs. 20%). Drawbacks and concerns are the small number (the original proposed sample size was 90) and the lack of any placebo effect on IEF and QoL. There were 4 men with MUI in the drug group and 5 in the placebo group. Results for SUI and UUI were not separated.

One would logically not expect improvement to continue after drug withdrawal unless a permanent change occurred in behavior, anatomy, or neuromuscular function. In another uncontrolled use study on men with post-RP SUI, Collado Serra and colleagues (2011) reported on 68 men whose median interval from surgery was 28.8 months. The reported results are somewhat confusing, but the overall impression is that some success was achieved. Treatment was intended to last for 9 months and restarted at 3 months if UI had worsened after cessation. The follow-up examinations were performed every 3 months, evaluating the symptoms, adverse effects, number of pads used daily, and International Consultation on Incontinence Questionnaire Urinary Incontinence Short Form (ICIQ-IU-SF) results. At the end of the first follow-up period, 39 (57%) of 68 patients had reduced the number of pads used daily. The pads per day nadir was achieved at the second follow-up visit in 29 (43%) of 68 patients, in 3 (8%) of 37 at visit 3, and 2 (12%) of 17 at visit 4. Once the nadir of success with treatment had been reached, the efficiency of duloxetine was maintained in 84% of patients and worsened in 16% despite continuing treatment. In this study, 25% of patients withdrew because of adverse events and 33% because of lack of effect.

Usage of duloxetine for SUI in men is universally off-label. A drug for this indication would be welcome. Larger, controlled, and better-designed studies are necessary to provide conclusive positive or negative data on this subject.

PHARMACOLOGIC THERAPY TO FACILITATE BLADDER EMPTYING

Increasing Intravesical Pressure and Bladder Contractility

Parasympathomimetic Agents

Because a major portion of the final common pathway in physiologic bladder contraction is stimulation of parasympathetic postganglionic muscarinic cholinergic receptor sites, agents that imitate the actions of ACh might be expected to be effective in treating patients who cannot empty the bladder because of inadequate bladder contractility. ACh, which is a quaternary amine, cannot be used for therapeutic purposes because of its action at both muscarinic and nicotinic receptors; it is rapidly hydrolyzed by acetylcholinesterase and by butyrylcholinesterase (Brown and Taylor, 2006). Many ACh-like drugs exist, but only bethanechol chloride exhibits a relatively selective in vitro action on the urinary bladder and gut with little or no nicotinic action (Brown and Taylor, 2006). Bethanechol is cholinesterase resistant and causes an in vitro contraction of smooth muscle from all areas of the bladder (see Chapter 69).

KEY POINTS: DRUGS FOR STRESS URINARY INCONTINENCE

- Pharmacologic efforts to increase outlet resistance in men and women have focused on increasing urethral tone or contractile ability at a peripheral or central level.
- The role of estrogen in the treatment of SUI has been somewhat controversial; however, the majority opinion seems to be that estrogen when given alone does not appear to be an effective treatment for SUI in the woman.
- The use of peripheral α -adrenergic agonists has largely been abandoned because of the adverse effects associated with these agents and the weak evidence of efficacy compared with placebo.
- Paradoxically, there are theoretic rationales for using both β -AR agonists and antagonists for treatment of SUI, but there are few data suggesting significant efficacy over control, and further well-designed randomized clinical trials are necessary.
- Duloxetine is a combined norepinephrine and serotonin reuptake inhibitor that increased sphincteric activity in an animal experimental model during the filling and storage phase of micturition. This compound has been widely tried in a variety of situations and using a variety of parameters. Some trials suggest statistical efficacy, more so in subjective data than objective data, and further research is needed regarding whether management policies incorporating this compound are clinically effective and cost-effective compared with other current approaches in women with varying degrees of SUI. Currently, duloxetine is licensed in the European Union for women with moderate to severe stress incontinence. It is approved in the United States for treatment of a variety of disorders, but was withdrawn from the approval process for the treatment of SUI.
- Effective pharmacologic management of SUI in men would be a welcome addition to the armamentarium, but this has received relatively little attention. There are a few clinical trials with interesting experimental designs and results, and it is obvious that larger, controlled, and better-designed studies are necessary to provide conclusive positive or negative data. The use of duloxetine for SUI in men is universally off-label.

Bethanechol, or agents similar to it, has historically been recommended for the treatment of postoperative or postpartum urinary retention, but only if the patient is awake and alert and if there is no outlet obstruction. The recommended dose has been 5 to 10 mg subcutaneously. For over 50 years, bethanechol has been recommended for the treatment of the atonic or hypotonic bladder and has been reported as effective in achieving "rehabilitation" of the chronically atonic or hypotonic detrusor (Sonda et al, 1979). Bethanechol has also been reported to stimulate or facilitate the development of reflex bladder contractions in patients in spinal shock secondary to suprasacral SCI (Perkash, 1975).

Although bethanechol has been reported to increase gastrointestinal motility and has been used in the treatment of gastroesophageal reflux, and although anecdotal success in specific patients with voiding dysfunction seems to occur, there was little or no evidence to support its success in facilitating bladder emptying in a series of patients in whom the drug was the only variable (Finkbeiner, 1985; Barendrecht et al, 2007). In one set of trials, a pharmacologically active subcutaneous dose (5 mg) did not demonstrate significant changes in flow parameters or residual urine volume in (1) a group of women with a residual urine volume greater than or equal to 20% of bladder capacity but no evidence of neurologic disease or outlet obstruction; (2) a group of 27 "normal" women of approximately the same age; or (3) a group of patients with a positive bethanechol supersensitivity test (Wein et al, 1980a, 1980b). This dose did increase cystometric filling pressure and also decreased

bladder capacity threshold, findings previously described by others (Sonda et al, 1979). Short-term studies in which the drug was the only variable have usually failed to demonstrate significant efficacy in terms of flow and residual urine volume data (Barrett, 1981). Farrell and colleagues (1990) conducted a double-blind randomized trial that looked at the effects of two catheter-management protocols and the effect of bethanechol on postoperative retention after gynecologic incontinence surgery. They concluded that bethanechol was not helpful at all in this setting. Although bethanechol is capable of eliciting an increase in bladder smooth muscle tension, as would be expected from *in vitro* studies, its ability to stimulate or facilitate a coordinated and sustained physiologic-like bladder contraction in patients with voiding dysfunction has been unimpressive (Finkbeiner, 1985; Andersson, 1988).

It is difficult to find reproducible urodynamic data that support recommendations for the use of bethanechol in any specific category of patients. Most, if not all, "long-term" reports in such patients are neither prospective nor double-blind and do not exclude the effects of other simultaneous regimens (such as treatment of urinary infection, bladder decompression, timed emptying, or other types of treatment affecting the bladder or outlet), an important observation to consider when reporting such drug studies. Whether repeated doses of bethanechol or any cholinergic agonist can achieve a clinical effect that a single dose cannot is speculative, as are suggestions that bethanechol has a different mode of action or effect on atonic or decompensated bladder muscle than on normal tissue.

Bethanechol administered subcutaneously does cause an increased awareness of a distended bladder and presumably the desire to void (Downie, 1984). This could facilitate more frequent emptying at lower volumes and thereby help to avoid overdistention, but, it would seem, only in a bladder that is capable of a contraction. O'Donnell and Hawkins (1993) administered 5 mg of bethanechol subcutaneously to 10 neurologically intact men and made the following cystometric observations: Bladder volume at first desire to void decreased (220 mL to 85 mL), maximal bladder capacity decreased (380 mL to 160 mL), first desire to void occurred at a higher pressure (5 cm H₂O vs. 28 cm H₂O), and compliance was reduced. They concluded that bethanechol affects the ability of the bladder to accommodate volume. Patients were comfortable at a resting bladder pressure of 20 cm H₂O (uncommon in their population), and the pressures at maximal bladder capacity were considerably higher than commonly seen under normal conditions. This suggested to them that either bladder pressure alone is not a significant factor in the perception of a sensation of first desire to void or that bethanechol somehow alters the threshold at which perception of desire to void occurs (because these patients showed a tolerance for increased intravesical pressure before first desire to void and at maximal bladder capacity). De Wachter and Wyndaele (2001) determined the bladder electrical threshold in healthy volunteers receiving 5 mg bethanechol subcutaneously. They found a marked decrease in the volume at which various filling sensations occurred and that the electrical threshold decreased after drug administration. De Wachter and colleagues (2003) treated 18 women with impaired detrusor contraction with subcutaneous bethanechol (5 mg four times daily) for 10 days. At the end of treatment 61% of the patients voided without a PVR volume. They also found that in these women the sensation of filling and the electrical sensitivity were significantly increased compared with before treatment. The authors suggested that patients likely to respond to bethanechol can be identified by determination of the bladder electrical perception threshold.

Riedl and colleagues (2000) performed a clinical study in 45 patients with detrusor areflexia. The patients were tested with electromotive administration of intravesical bethanechol. Bethanechol 25 mg given orally once daily was then prescribed for 15 patients, and voiding control was assessed after 6 weeks of therapy. A mean pressure increase of 34 cm H₂O during the electromotive administration of bethanechol was found in 24 of 26 patients with areflexia and neurologic disease compared with only 3 cm H₂O in 3 of 11 with a history of chronic bladder dilation. Oral bethanechol restored

spontaneous voiding in 9 of 11 patients who had had a positive response to the electromotive administration of bethanechol, whereas all 4 without a pressure increase during the electromotive administration of bethanechol did not void spontaneously. The researchers concluded that electromotive administration of intravesical bethanechol can identify patients with an atonic bladder and adequate residual detrusor muscle function who are candidates for restorative measures, such as oral bethanechol and intravesical electrostimulation. Those who do not respond to the electromotive administration of bethanechol do not benefit from oral bethanechol and are candidates for catheterization.

No agreement exists as to whether cholinergic stimulation produces an increase in urethral resistance (Wein et al, 1980a, 1980b). It would appear that pharmacologically active doses, in fact, do increase urethral closure pressure, at least in patients with NDO (Sporer et al, 1978). This would of course tend to inhibit bladder emptying. As to whether cholinergic agonists can be combined with agents to decrease outlet resistance to facilitate emptying and achieve an additive or synergistic effect, our own experience with such therapy, using even 200 mg (50 mg qid) of oral bethanechol daily, has been disappointing. Certainly, most clinicians would agree that a total divided daily dose of 50 to 100 mg rarely affects any urodynamic parameter at all. In a prospective, single-blind randomized study consisting of 119 patients with underactive detrusor, Yamanishi and colleagues (2004) studied the effect of combination of a cholinergic drug (bethanechol 60 mg daily or distigmine 15 mg daily) and an α -AR antagonist (urapidil 60 mg daily). The effectiveness of each therapy was assessed 4 weeks after initialization of the therapy using IPSS. IPSS remained unchanged after the cholinergic therapy, but was significantly lower after the α -AR antagonist treatment and the combination therapy. With regard to the total IPSS, there were significant differences between the cholinergic and the α -AR antagonist groups, and also between the cholinergic and combination groups, in favor of the latter. The average and maximum flow rates did not increase significantly after monotherapy with either the cholinergic drug or the α -AR antagonist, but they significantly increased after combination therapy compared with baseline values. PVR volume did not decrease significantly after the cholinergic drug therapy but decreased significantly after the α -AR antagonist and the combination therapies. The authors concluded that combination therapy with a cholinergic drug and an α -AR antagonist appeared to be more useful than monotherapy for the treatment of underactive detrusor.

The question of whether bethanechol may be efficacious in a particular patient can be answered by a brief uroynamically controlled trial in which institution of therapy is the only variable. In the laboratory, a functioning micturition reflex is an absolute requirement for the production of a sustained bladder contraction by a subcutaneous injection of the drug (Downie, 1984). Patients with incomplete lower motoneuron lesions constitute the most reasonable group for a trial of bethanechol (Awad, 1985), although subcutaneous administration may be required. It is generally agreed that, at least in a "denervated" bladder, an oral dose of 200 mg is required to produce the same urodynamic effects as a subcutaneous dose of 5 mg (Diokno and Lapidus, 1977).

The potential side effects of cholinomimetic drugs include flushing, nausea, vomiting, diarrhea, gastrointestinal cramps, bronchospasm, headache, salivation, sweating, and difficulty with visual accommodation (Brown and Taylor, 2006). Intramuscular and intravenous use can precipitate acute and severe side effects, resulting in acute circulatory failure and cardiac arrest, and are therefore prohibited. Contraindications to the use of this general category of drug include bronchial asthma, peptic ulcer, bowel obstruction, enteritis, recent gastrointestinal surgery, cardiac arrhythmia, hyperthyroidism, and any type of BOO.

One potential avenue of increasing bladder contractility is cholinergic enhancement or augmentation. Such an action might be useful alone or in combination with a parasympathomimetic agent. Metoclopramide is a dopamine-receptor antagonist with cholinergic properties (Pasricha et al, 2006). It has a central antiemetic effect

in the chemoreceptor trigger zone and peripherally increases the tone of the lower esophageal sphincter, promoting gastric emptying. Its effects seem to be related to its ability to antagonize the inhibitory action of dopamine, to augment ACh release, and to sensitize the muscarinic receptors of gastrointestinal smooth muscle. Some data from dogs suggest that this agent can increase detrusor contractility (Mitchell and Venable, 1985), but there are no controlled studies documenting a useful clinical effect in the treatment of detrusor underactivity.

Cisapride is a substituted piperidinyl benzamide with a number of different pharmacologic activities, including a possible direct stimulation of smooth muscle (Pasricha, 2006). Until recently it was commonly used as a prokinetic agent, particularly for gastroesophageal reflux and gastroparesis. It was also suggested that it could improve bladder contractility (Binnie et al, 1988; Carone et al, 1993; Steele et al, 2001). However, there was never any particularly convincing data that the drug improved voiding function, and it is no longer available in the United States because of its potential to induce serious and occasional cardiac arrhythmias (Pasricha, 2006). The concept, however, of cholinergic enhancement or augmentation remains attractive but awaits the development of a bladder-selective compound.

Prostaglandins

The reported use of prostaglandins to facilitate emptying is based on hypotheses that these substances contribute to the maintenance of bladder tone and bladder contractile activity (see Chapter 69 and Andersson, 1993; Zderic et al, 1995; Andersson, 1999a, 1999b, 1999c; Andersson and Wein, 2004 for a complete discussion). Prostaglandins and thromboxane A_2 (TXA_2) have been shown to be present in human bladder in the following quantitative order: $PGE_2 > PGE_1 > PGF_{2\alpha} > TXA_2$; isolated detrusor muscle is contracted by $PGF_{2\alpha}$, PGE_1 , PGE_2 , and TXA_2 (see references in Andersson and Wein, 2004). Prostanoids are synthesized locally in both bladder muscle and mucosa, with synthesis being initiated by various physiologic stimuli such as detrusor muscle stretch, mucosal injury, neural stimulation; by ATP; and by mediators of inflammation (Andersson and Wein, 2004). Prostanoids may affect bladder activity directly by effects on the smooth muscle or indirectly through effects on neurotransmission. Possible roles mentioned by Andersson (2000b) include (1) neuromodulators of efferent and afferent neurotransmission; (2) sensitization or perhaps (3) activation of certain sensory nerves; and (4) potentiation of ACh release from cholinergic nerve terminals through prejunctional prostanoid receptors. PGE_2 seems to cause a net decrease in urethral smooth muscle tone; $PGF_{2\alpha}$ causes an increase.

Bultitude and colleagues (1976) first reported that instillation of 0.5 mg of PGE_2 into the bladders of female patients with varying degrees of urinary retention resulted in acute emptying and in improvement of longer-term emptying (several months) in two thirds of the patients studied ($N = 22$). Desmond and colleagues (1980) reported results with intravesical use of 1.5 mg of this agent (diluted with 20 mL of 0.2% neomycin solution) in patients whose bladders exhibited no contractile activity or in whom bladder contractility was relatively impaired. Twenty of 36 patients showed a strongly positive immediate response, and 6 showed a weakly positive one. Fourteen patients were reported to show prolonged beneficial effects, all but 1 of whom had shown a strongly positive immediate response. Stratification of the data revealed that an intact sacral reflex arc was a prerequisite for any type of positive response. Tammela and colleagues (1987) reported that one intravesical administration of 10 mg of $PGF_{2\alpha}$ facilitated voiding in women who were in retention 3 days after surgery for SUI. The drug was administered in 50 mL of saline solution as a single dose and retained for 2 hours. However, in these "successfully" treated patients, the average maximum flow rate was 10.6 mL/sec with a mean residual urine volume of 107 mL, and the authors stated that "bladder emptying deteriorated in most patients on the day after treatment." Koonings and colleagues (1990) reported that daily intravesical

$PGF_{2\alpha}$ and intravaginal PGE_2 reduced the number of days required for catheterization after stress incontinence surgery when compared with a control group receiving intravesical saline solution.

Others, however, have reported negative results. Grignaffini and Bazzani (1998) reported on instillation of 1.5 mg of PGE_2 in 50 mL of saline solution into the bladder of 50 patients on their fourth day after vaginal hysterectomy and cystourethropepy, with a control group of 60 patients. The results are presented in an interesting fashion. After catheter removal, following the PGE_2 or control treatment, 58% of the PGE_2 -treated group voided spontaneously as compared with 48.3% of the control group. This difference was not significant. Thus 42% of the treated group and 51.7% of the control group were in retention. Of those who were in retention, the number who were in retention for less than 3 days was greater in the PGE_2 group (32%) versus the control group (25%), and this was statistically significant. Likewise, the number who remained in urinary retention for 3 days or longer after the initial treatment was 10% in the PGE_2 -treated group versus 26.7% in the control group. Stanton and colleagues (1979) and Delaere and colleagues (1981) reported on success using intravesical PGE_2 in doses similar to those reported earlier; Delaere and colleagues (1981) similarly reported no success using $PGF_{2\alpha}$ in a group of women with emptying difficulties of various causes. Wagner and colleagues (1985) used PGE_2 in doses of 0.75 to 2.25 mg and reported no effect on urinary retention in a group of patients after anterior colporrhaphy.

In a prospective randomized double-blind study, Hindley and colleagues (2004) tested the hypothesis that the combination of intravesical PGE_2 and oral bethanechol is additive or synergistic in improving bladder emptying. Nineteen patients with detrusor underactivity (17 men and 2 women) were eligible and randomized to one of two treatments. One group (9 patients) received once-weekly intravesical PGE_2 (1.5 mg in 20 mL of 0.9% saline) plus bethanechol 50 mg four times daily, for a total of 6 weeks. A second group of 10 patients received a once-weekly instillation of saline together with placebo tablets, again for 6 weeks. Although there was evidence of a pharmacologic effect, bethanechol and PGE_2 had a limited therapeutic effect compared with placebo. The authors did not recommend this treatment as routine but suggested that it may be considered for the occasional treatment of a patient with detrusor underactivity.

There has been little recent activity in this area, a fact that usually means that clinicians have lost interest or that the initial optimistic results have not been confirmed. Prostaglandins have a relatively short half-life, and it is difficult to understand how any effects after a single application can last up to several months. If such does occur, it must be the result of a "triggering effect" on some as yet unknown physiologic or metabolic mechanism. Because of the number of conflicting positive and negative reports with various intravesical preparations, double-blind, placebo-controlled studies would obviously be helpful to see whether there are circumstances in which prostaglandin use can reproducibly facilitate emptying or treat postoperative retention. Potential systemic side effects of prostaglandin use include vomiting, diarrhea, pyrexia, hypertension, and hypotension (Campbell and Halushka, 1996).

Blockers of Inhibition

de Groat and coworkers (see Chapter 69; de Groat et al, 1993, 1999; Zderic et al, 1995; de Groat, 1997) have demonstrated a sympathetic reflex during bladder filling that, at least in the cat, promotes urine storage partly by exerting an α -AR-mediated inhibitory effect on pelvic parasympathetic ganglionic transmission. Some have suggested that α -AR blockade, in addition to decreasing outlet resistance, may in fact facilitate transmission through these ganglia and thereby enhance bladder contractility. On this basis, Raz and Smith (1976) were the first to advocate a trial of an α -AR blocking agent for the treatment of nonobstructive urinary retention. A complete discussion of postoperative retention, including the use of α -AR antagonists for its treatment, is presented elsewhere (see Chapter 65).

Opioid-Receptor Antagonists

Endogenous opioids have been hypothesized to exert a tonic inhibitory effect on the micturition reflex at various levels (see Chapter 69; Zderic et al, 1995), and agents such as opioid-receptor antagonists therefore may offer possibilities for stimulating reflex bladder activity.

Thor and associates (1983) were able to stimulate a micturition contraction with naloxone, an opioid-receptor antagonist, in unanesthetized cats with chronic SCI. The effects, however, were transient, and tachyphylaxis developed. Vaidyanathan and colleagues (1981) reported that an intravenous injection of 0.4 mg of naloxone enhanced detrusor reflex activity in 5 of 7 patients with neuropathic bladder dysfunction caused by incomplete suprasacral spinal cord lesions. The maximum effect occurred within 1 to 2 minutes after intravenous injection and was gone by 5 minutes. Murray and Feneley (1982) reported that the same dose of naloxone caused, in a group of patients with IDO, an increase in detrusor pressure at zero volume and at first desire to void, a decrease in the maximum cystometric capacity, and a worsening of the degree of instability. Galeano and colleagues (1986) reported that although naloxone increased bladder contractility in cats with chronic spinal injury, it also aggravated striated sphincter dyssynergia and spasticity—a potential problem in the treatment of emptying failure. Wheeler and colleagues (1987) noted no significant cystometric changes in a group of 15 SCI patients after intravenous naloxone, whereas 11 showed decreased perineal EMG activity. Although an intriguing area, the concept of reversing an inhibitory opioid influence to stimulate reflex bladder activity is of little practical use at present.

KEY POINTS: TREATMENT OF DETRUSOR UNDERACTIVITY

- A pharmacologic agent that is effective for the treatment of detrusor underactivity or underactive bladder would be welcome. It is difficult to find reproducible urodynamic data that support a recommendation for the use of oral bethanechol chloride in any specific category of patients, despite its pharmacologic characteristics as a cholinergic agonist. It is possible that bethanechol, by increasing static intravesical pressure, may cause afferent stimulation at a lower bladder volume than usual, prompting detrusor contraction at a more favorable bladder volume. Such an action would be expected to occur only in bladders that were not truly acontractile.
- Prostaglandins could theoretically facilitate bladder activity either directly by effects on the smooth muscle or indirectly through effects on neurotransmission or increased sensitization to filling stimuli. Initial reports of the use of intravesical prostanoids producing lasting favorable clinical effects have not been confirmed. Work continues on oral agents.

Decreasing Outlet Resistance

Decreasing Outlet Resistance at a Site of Anatomic Obstruction

This topic includes the treatment of BOO secondary to BPE. A full discussion is appropriately included in Chapter 104.

Decreasing Outlet Resistance at the Level of the Smooth Sphincter

α -Adrenoceptor Antagonists. Whether or not one believes that there is significant innervation of the bladder and proximal urethral smooth musculature by postganglionic fibers of the sympathetic nervous system, one must acknowledge the existence of α - and β -AR sites. The smooth muscle of the bladder base and proximal urethra contains predominantly α -ARs, although β -ARs are present. The bladder body contains both varieties of ARs, with

β -ARs (β_3) being more common (see Chapter 69; Zderic et al, 1995; Andersson, 2000b). The human LUT contains more α_2 - than α_1 -ARs, but adrenergically induced prostatic smooth muscle contraction and human LUT smooth muscle contraction are mediated largely, if not exclusively, by α_1 -ARs. There are at least three subtypes of α_1 -ARs, designated α_{1A} , α_{1B} , and α_{1D} . Adrenergically induced smooth muscle contraction in the human LUT is mediated largely by the α_{1A} (and in the detrusor α_{1D}) subtype (Docherty, 1998; Harada and Fujimura, 2000; Andersson and Wein, 2004; Michel and Vrydag, 2006; Andersson and Gratzke, 2007; Yamada and Ito, 2011). In addition to the three cloned α_1 -ARs, there is a possible fourth, α_{1L} , although the α_{1L} -AR is probably a variant of the α_{1A} type. There is a tremendous amount of information and controversy in the literature regarding the selectivity of certain α -AR blocking agents for these respective receptor subtypes. Conclusions are drawn regarding the “best” α_1 -AR antagonist for the treatment of at least BPH on the basis of in vitro and in vivo pharmacologic selectivity, but many authors note that this does not necessarily translate into functional selectivity in a given patient (Andersson, 2002c; Djavan et al, 2004). The various α -AR antagonists are dealt with in more detail in Chapter 104.

Krane and Olsson (1973) were among the first to promote the concept of a physiologic internal sphincter partially controlled by tonic sympathetic stimulation of contraction-mediating α -ARs in the smooth musculature of the bladder neck and proximal urethra. Furthermore, they hypothesized that some obstructions at this level during bladder contraction are a result of inadequate opening of the bladder neck and/or of an inadequate decrease in resistance in the area of the proximal urethra. They also theorized and presented evidence that α -AR blockade could be useful in promoting bladder emptying in such a patient with an adequate detrusor contraction but without anatomic obstruction or detrusor striated sphincter dyssynergia. They and many others (see Wein and Barrett, 1988) have confirmed the usefulness of α -AR blockade in the treatment of what is now usually referred to as *smooth sphincter or bladder neck dyssynergia or dysfunction*. Successful results, usually defined as an increase in flow rate, a decrease in residual urine, and an improvement in upper tract appearance (where pathologic), could often be correlated with an objective decrease in urethral profile closure pressure.

One would expect success with such therapy to be most evident in patients without detrusor striated sphincter dyssynergia, as reported by Hachen (1980). Mobley (1976), however, reported a startling 86% subjective success rate in 21 patients with a reflex neurogenic bladder, with a corresponding success rate of 66% in what was called “flaccid” and 57% of what was called “autonomous” neurogenic bladder dysfunction, with success being defined as PVR urine volume consistently less than 100 mL. Scott and Morrow (1978), on the other hand, noted excellent results with phenoxybenzamine therapy in 9 of 10 patients with a flaccid bladder and a flaccid external sphincter and in a single patient with an upper motor neuron bladder with intact sympathetic innervation, but in only 8 of 21 patients with hyperreflexia and autonomic dysreflexia, and in none of 6 patients with an upper motor neuron bladder and sympathetic denervation (lesion between T10 and L2).

Although most would agree that α -AR blocking agents exert their favorable effects on voiding dysfunction by affecting the smooth muscle of the bladder neck and proximal urethra, information in the literature suggests that they may decrease striated sphincter tone as well, and other information suggests that they may exert some of their effects on at least the filling and storage symptoms of voiding dysfunction by decreasing bladder contractility (see previous discussion). Much of the confusion relative to whether α -AR blocking agents have a direct (as opposed to indirect) inhibitory effect on the striated sphincter relates to the interpretation of clinical observations and experimental data referable to their effect on urethral pressure in the region of the urogenital diaphragm and on electromyographic activity in the periurethral striated muscle of this area. One cannot tell by pressure tracings alone whether decreased resistance in this area of the urethra is secondary to a decrease in smooth or striated muscle activity. Nanninga and colleagues (1977)

found that the electromyographic activity of the external sphincter decreased after phentolamine administration in three paraplegic patients and attributed this effect to a direct inhibition of sympathetic action on the striated sphincter. [Nordling and colleagues \(1981\)](#) demonstrated that clonidine and phenoxybenzamine (both of which pass the blood-brain barrier) also decreased urethral pressure in this area and yet had no effect on EMG activity. They concluded (1) that the effect of phentolamine was from smooth muscle relaxation alone; (2) that the effect of clonidine, and possibly phenoxybenzamine, was elicited mostly through centrally induced changes in striated urethral sphincter tonus; and (3) that these agents also had an effect on the smooth muscle component of urethral pressure. None of the three drugs, however, affected the reflex rise in either urethral pressure or electromyographic activity seen during bladder filling, and none decreased the urethral pressure or electromyographic activity response to voluntary contraction of the pelvic floor striated musculature. [Gajewski and colleagues \(1984\)](#) concluded that α -AR blockers do not influence the pudendal nerve-dependent urethral response in the cat through a peripheral action but that at least prazosin can significantly inhibit this response at a central level. [Thind and colleagues \(1992\)](#) reported on the effects of prazosin on static urethral sphincter function in 10 healthy women. They found a reduction—predominantly in the midurethral area—and hypothesized that the response was caused by a decrease in both smooth and striated sphincter activity, the latter as a result of reduced somatomotor output from the CNS. Clinically, [Chancellor and colleagues \(1994\)](#) reported that terazosin, a selective α_1 -AR antagonist, had little or no effect on striated sphincter function in SCI patients and had no effect on functional obstruction caused by sphincter dyssynergia in these patients.

α -AR blocking agents have also been used to treat both bladder and outlet abnormalities in patients with so-called autonomous bladders—such as those with myelodysplasia, sacral spinal cord or infrasacral neural injury, and voiding dysfunction after radical pelvic surgery ([Wein and Barrett, 1988](#)). Decreased bladder compliance is a common clinical problem in such patients, and this, along with a fixed urethral sphincter tone, results in the paradoxical occurrence of both storage and emptying failure.

Specific α -adrenergic blocking agents are discussed fully in Chapter 104 with reference to management of BPO. A brief description can be found on the Expert Consult website.

Decreasing Outlet Resistance at the Level of the Striated Sphincter

There is no class of pharmacologic agents that will selectively relax the striated musculature of the pelvic floor. Three different

types of drugs have been used to treat voiding dysfunction secondary to outlet obstruction at the level of the striated sphincter: the benzodiazepines, dantrolene, and baclofen.

The use of these is discussed in detail on the Expert Consult website.

KEY POINTS: DECREASING OUTLET RESISTANCE

- α -Adrenergic blocking agents are capable of reducing smooth muscle tone in the bladder outlet in both men and women and in the prostatic muscle. Such agents can be used with success in patients with bladder neck dysfunction and in men with BOO secondary to prostatic enlargement. Blockade of the α_{1A} -AR would theoretically exert the greatest effect, and whether there is any difference in the efficacy of the individual agents available remains a topic of controversy.
- There is no class of pharmacologic agents that will selectively relax the striated musculature of the pelvic floor. There are few references that provide any information regarding efficacy of the benzodiazepines for this purpose. Baclofen seems to be most useful when administered intrathecally; dantrolene is seldom if ever used for this purpose. Injection of botulinum toxin into the striated sphincter has been used with some clinical success, especially in patients with neurologic striated sphincter dyssynergia. The potential for spread to nearby structures is greater than with intravesical therapy, and distant effects can also occur, but these are rare.

Phenoxybenzamine. Phenoxybenzamine was the α -AR antagonist originally used for the treatment of voiding dysfunction (see Te, 2002). Phenoxybenzamine has blocking properties at both α_1 - and α_2 -AR sites. The initial adult dose of this agent is 10 mg/day, and the usual daily dose for voiding dysfunction is 10 to 20 mg. After discontinuation, the effects of administration may persist for days, because the drug irreversibly inactivates α -ARs and the duration of effect depends on the rate of receptor synthesis (Hoffman and Lefkowitz, 1996). Side effects affect approximately 30% of patients (Kirby, 1999) and include orthostatic hypotension, reflex tachycardia, nasal congestion, diarrhea, miosis, sedation, nausea, and vomiting (secondary to local irritation). It has mutagenic activity in the Ames test, and repeated administration to animals can cause peritoneal sarcomas and lung tumors (Westfall and Westfall, 2006). Although this agent has been in clinical use for some 35 years without clinically apparent oncologic associations, one must now consider the potential medicolegal ramifications of long-term therapy, especially in younger persons. A reassessment of the use of phenoxybenzamine for treatment of urinary tract disorders was made by Te (2002). It is seldom used at present.

Prazosin. Prazosin was the first potent selective α_1 -AR antagonist (see Westfall and Westfall, 2006) used to lower outlet resistance (Andersson et al, 1981). The duration of action is 4 to 6 hours; therapy is usually begun in daily divided doses of 2 to 3 mg. The dose may be very gradually increased to a maximum of 20 mg daily, although seldom has anyone used more than 9 to 10 mg daily for voiding dysfunction. The potential side effects of prazosin are consequent to its α_1 -AR blockade. Occasionally, there occurs a "first-dose phenomenon," a symptom complex of faintness, dizziness, palpitation, and, infrequently, syncope, thought to be caused by acute postural hypotension. The incidence of this can be minimized by restricting the initial dose of the drug to 1 mg and administering this at bedtime. Other side effects associated with chronic prazosin therapy are usually mild and rarely necessitate withdrawal of the drug.

Terazosin and Doxazosin. Terazosin and doxazosin are two highly selective postsynaptic α_1 -AR antagonists. They are readily absorbed with high bioavailability and a long plasma half-life, enabling their activity to be maintained over 24 hours after a single oral dose. Both of these agents have been evaluated with respect to their efficacy in patients with LUTS and decreased flow rates presumed secondary to BPH. Their efficacy in decreasing symptoms and raising flow rates has been shown to be superior to placebo and similar to that of prazosin (Kirby, 1999; Lepor et al, 2012). Their safety profiles have been well documented as a result of their widespread use over several years for the treatment of hypertension. Side effects are related to peripheral vasodilation (postural hypotension), and both drugs have to be started at a low dose and titrated to obtain an optimum balance between efficacy and tolerability. Dizziness and weakness are sometimes observed, and these are presumed secondary to CNS actions. These drugs are marketed for the treatment of hypertension as well as LUTS presumed secondary to BPH.

Alfuzosin and Tamsulosin. Alfuzosin and tamsulosin, both highly selective α_1 -AR blockers, have appeared and are marketed solely for the treatment of BPH because of some reports suggesting preferential action on prostatic rather than vascular smooth muscle (Kirby, 1999; Djavan et al, 2004; Lepor et al, 2012). Marketing claims aside, whether there is any difference in the efficacy or side effect profiles of these individual agents remains a topic of controversy. Both are able to be administered once daily and without titration. Available data suggest that retrograde ejaculation and rhinitis are more common with tamsulosin and silodosin, whereas dizziness and asthenia are more common with terazosin and doxazosin (Kirby et al, 2000; Djavan et al, 2004; Lepor et al, 2012).

Silodosin. Silodosin is a novel, highly selective α_{1A} -AR antagonist (Yoshida et al, 2007). Clinical data (Kawabe et al, 2006; Chapple et al, 2011; Novara et al, 2013) showed that silodosin showed significant improvement in LUTS associated with BPH, as well as in QoL. The improvements were observed in both voiding and storage symptoms. Long-term study revealed that the efficacy and safety were sustained for 1 year. The most common adverse event in the silodosin group was abnormal ejaculation, which occurred in 22% of patients (Kawabe et al, 2006). Adverse events associated with lowering of blood pressure were low.

Thus, agents with α -AR blocking properties at various levels of neural organization have been used in patients with very varied types of voiding dysfunction—functional outlet obstruction, urinary retention, decreased compliance, and DO. Our own experience would suggest that a trial of such an agent is certainly worthwhile, because the effect or lack of effect will become obvious in a matter of days, and any pharmacologic side effects are, of course, reversible. However, our results with such therapy for non-BPH-related voiding dysfunction have been somewhat less spectacular than those of at least some other investigators.

Nitric Oxide. In the future there may be other pharmacologic mechanisms that are explored to produce relaxation in the smooth muscle of the bladder neck, urethra, or prostatic stroma. Nitric oxide is a neurotransmitter capable of producing smooth muscle relaxation, at least in the female rabbit urethra, pig urethra, and human bladder neck (Andersson and Persson, 1993; Andersson and Wein, 2004). A selective nitrergic action on bladder neck and urethral smooth muscle is an interesting theoretic possibility. Mumtaz and colleagues (2000) suggested that a topical intraurethral NO donor could induce urethral smooth muscle relaxation without affecting bladder smooth muscle function and that this is a possible clinical avenue of exploration. Mamas and colleagues (2001, 2003) hypothesized that augmentation of external sphincter NO could be an effective pharmacologic treatment for DSD. In a functional urodynamic study, Reitz and colleagues (2004a) assessed the effect of the NO donor isosorbide dinitrate on the external urethral sphincter. Magnetic stimulation of the sacral roots was performed in eight healthy men to evoke reproducible contractions of the external urethral sphincter. Sublingual administration of isosorbide dinitrate (10 mg) could significantly reduce the resting pressure of the external urethral sphincter for at least 1 hour. The maximal contractile strength measured as the maximal urethral pressure during single pulse and continuous magnetic stimulation of the sacral roots also decreased significantly. NO did not induce a significantly faster fatigue of the external urethral sphincter during continuous magnetic stimulation of the sacral roots. The authors suggested that NO donors could offer a new pharmacologic approach to treat urinary retention caused by an overactive or non-relaxing external urethral sphincter. In a later study on 12 male SCI patients with NDO and DSD, Reitz and colleagues (2004b) found that NO significantly reduced external urethral sphincter pressures at rest ($P < .05$) and during dyssynergic contraction ($P < .05$), whereas bladder pressures at rest and during contraction as well as the reflex volume remained unchanged. In patients who used suprapubic tapping for bladder emptying, the mean post-triggering residual volume was significantly reduced ($P < .05$). The researchers concluded based on their findings that NO donors could offer a potential pharmacologic option to treat DSD in SCI patients.

The benzodiazepines are classified both as antianxiety agents (Baldessarini, 2006) and as sedative-hypnotics, muscle relaxants, and anticonvulsants (Charney et al, 2006). Dantrolene and baclofen are characterized as antispasticity agents (Standaert and Young, 2006; Taylor, 2006). Baclofen and diazepam exert their actions predominantly within the CNS, whereas dantrolene acts directly on skeletal muscle. Unfortunately, **there is no completely satisfactory form of therapy for alleviation of skeletal muscle spasticity.** Although these drugs are capable of providing variable relief in given circumstances, their efficacy is far from complete; and troublesome muscle weakness, adverse effects on gait, and a variety of other side effects minimize their overall usefulness as treatments of spasticity (Standaert and Young, 2006; Taylor, 2006).

GABA and glycine have been identified as major inhibitory transmitters in the CNS (Andersson and Wein, 2004; Bloom, 2006). GABA is the most widely distributed inhibitory neurotransmitter in the mammalian CNS. GABA receptors have been divided into three types. The GABA-A receptor directly gates a chloride ionophore and has modulatory binding sites for benzodiazepines, barbiturates, neurosteroids, and ethanol (Bloom, 2006). The GABA-B or metabotropic receptor couples to calcium and potassium channels by means of G proteins and second messenger systems. It inhibits adenylate cyclase, activates potassium channels, and reduces calcium conductance. The GABA-B receptor is activated by baclofen and is resistant to drugs that modulate GABA-A receptors. There is a third class of GABA receptors, the GABA-C receptor, which is less widely distributed than the A and B subtypes (Bloom, 2006). GABA appears to mediate the inhibitory actions of local interneurons in the brain and presynaptic inhibition within the spinal cord (Bloom, 2006). Glycine receptors are prominent in the brainstem and spinal cord and have many features analogous to the GABA-A receptor.

Benzodiazepines. Benzodiazepines potentiate the action of GABA by promoting GABA binding to the GABA-A receptor (Baldessarini, 2006; Charney et al, 2006). Benzodiazepines are extensively used for the treatment of anxiety and related disorders (Baldessarini, 2006), although pharmacologically they can also be classified as centrally acting muscle relaxants. The generalized anxiety disorder that is responsive to pharmacotherapy with these agents is characterized by unrealistic and/or excessive anxiety and worry about life circumstances (Shader and Greenblatt, 1993). Specific symptoms can be related to motor tension, autonomic hyperactivity (frequent urination can be a manifestation of this, as well as nausea, vomiting, diarrhea, and abdominal distress), and excessive vigilance. Other common uses have included treatment of insomnia, stress-related disorders, muscle spasm, and epilepsy and as preoperative sedation (Lader, 1987). Side effects include nonspecific CNS depression manifesting as sedation, lethargy, drowsiness, a feeling of slowing of thought processes, ataxia, and decreased ability to acquire or store information (Shader and Greenblatt, 1993; Baldessarini, 2006). Some believe that any muscle relaxation effect in clinically used doses is caused by the CNS depressant effects and cite a lack of clinical studies showing any advantages of these agents over placebo or aspirin in this regard (Baldessarini, 2006; Charney et al, 2006). Effective total daily doses of diazepam, the most widely used agent of this group, range from 4 to 40 mg. Other benzodiazepine anxiolytic agents include chlorthalidoxepoxide, clorazepate, prazepam, halazepam, clonazepam, lorazepam, oxazepam, and alprazolam.

Few references are available that provide evaluable data on the use of any of the benzodiazepines in the treatment of functional obstruction at the level of the striated sphincter. Opinions, however, are commonly expressed, at least with regard to diazepam. We have not found the recommended oral doses of diazepam to be effective in controlling the classic type of detrusor striated sphincter dyssynergia secondary to neurologic disease. If the cause of incomplete emptying in a neurologically normal patient is obscure and the patient has what appears to be inadequate relaxation of the pelvic floor striated musculature urodynamically (e.g., dysfunctional voiding, occult neuropathic bladder, the Hinman syndrome), a trial of such an agent may be worthwhile. The rationale for use is

either that of relaxation of the pelvic floor striated musculature during bladder contraction or that such relaxation removes an inhibitory stimulus to reflex bladder activity. Improvement under such circumstances may simply be caused, however, by the antianxiety effect of the drug, or by the intensive explanation, encouragement, and modified biofeedback therapy that usually accompanies such treatment in these patients.

Baclofen. Baclofen depresses monosynaptic and polysynaptic excitation of motoneurons and interneurons in the spinal cord by activating GABA-B receptors (Standaert and Young, 2006). Baclofen's primary site of action is in the spinal cord, but it is also reported to have activity at more rostral sites in the CNS. Baclofen has been found useful in the treatment of skeletal spasticity from a variety of causes (especially amyotrophic lateral sclerosis (Standaert and Young, 2006). Determination of the optimal dose in an individual patient requires careful titration. Treatment is started at an initial dose of 5 mg twice daily, and the dose is increased every 3 days up to a maximum daily dose of 20 mg four times a day. With reference to voiding dysfunction, Hachen and Krucker (1977) found a daily oral dose of 75 mg ineffective in patients with striated sphincter dyssynergia from traumatic paraplegia, whereas they found a daily intravenous dose of 20 mg highly effective. Florante and colleagues (1980) reported that 73% of their patients with voiding dysfunction secondary to acute and chronic SCI showed lower striated sphincter responses and decreased residual urine volumes after baclofen treatment, but only with an average daily oral dose of 120 mg. Potential side effects of baclofen include drowsiness, insomnia, rash, pruritus, dizziness, and weakness. It may impair ability to walk or stand and is not recommended for the management of spasticity caused by cerebral lesions or disease. Sudden withdrawal has been shown to provoke hallucinations, anxiety, and tachycardia; hallucinations during treatment, which have been responsive to reductions in dosage, have also been reported (Roy and Wakefield, 1986).

Drug delivery often frustrates adequate pharmacologic treatment, and baclofen is a good example of this. GABA's hydrophilic properties prevent its crossing the blood-brain barrier in sufficient amounts to make it therapeutically useful. For oral use, the more lipophilic analogue, baclofen, was developed. However, its passage through the barrier is likewise limited, and it has proved to be a generally insufficient drug when given orally to treat severe somatic spasticity and micturition disorders secondary to neurogenic dysfunction (Kums and Delhaas, 1991).

Intrathecal infusion bypasses the blood-brain barrier; CSF levels 10 times higher than those reached with oral administration are achieved with infusion amounts 100 times less than those taken orally (Penn et al, 1989). Direct administration into the subarachnoid space by an implanted infusion pump showed initially promising results for not only skeletal spasticity but also striated sphincter dyssynergia and DO.

Nanninga and colleagues (1989) reported on such administration to seven patients with intractable spasticity. All patients experienced a general decrease in spasticity, and the amount of striated sphincter activity during bladder contraction decreased; six showed an increase in bladder capacity. Four previously incontinent patients were able to stay dry with CIC. The action on DO is not unexpected, given its spinal cord mechanism of action, and this inhibition of bladder contractility when the drug is administered intrathecally may in fact prove to be its most important benefit. Laubser and colleagues (1991) studied nine SCI patients with refractory spasticity, using an external pump to initially test response. Eight showed objective improvement in functional abilities; three of seven studied urodynamically showed an increase in bladder capacity. Kums and Delhaas (1991) reported on nine paraplegic or quadriplegic men (secondary to trauma or MS) with intractable muscle spasticity treated with intrathecal baclofen. After a successful test period through an external catheter, a drug delivery system was implanted and connected to a spinal catheter. Doses per 24 hours ranged from 74 to 840 µg. Patients were studied before and 4 to 6 weeks after initiation of therapy. Mean residual urine volume fell from 224 to

110 mL ($P = .01$), mean urodynamic bladder capacity rose from 162 to 263 mL ($P = .005$), and pelvic floor spasm decreased at both baseline and at maximum bladder capacity ($P = .005$ and $P = .025$, respectively). Three subjects became continent. In addition, CIC was no longer complicated by adductor spasm. [Bushman and colleagues \(1993\)](#) reported an increase in bladder storage in three individuals with hereditary spastic paraplegia treated with intrathecal baclofen. Tolerance to intrathecal baclofen with a requirement for increasing doses may prove to be a problem with long-term chronic use, and studies are underway to investigate this. [Vaidyanathan and colleagues \(2004\)](#) reported a case with insidious development of autonomic dysreflexia and hydronephrosis resulting from dyssynergic voiding after discontinuation of intrathecal baclofen therapy. They recommended that in SCI patients in whom intrathecal baclofen therapy is terminated, close monitoring of the urologic status is needed.

Dantrolene. Dantrolene exerts its effects by a direct peripheral action on skeletal muscle ([Standaert and Young, 2006](#); [Taylor, 2006](#)). It is thought to inhibit the excitation-induced release of calcium ions from the sarcoplasmic reticulum of striated muscle fibers, thereby inhibiting excitation-contraction coupling and diminishing the mechanical force of contraction. The blockade of calcium release is not complete, however, and contraction is not completely abolished. It reduces reflex more than voluntary contraction, probably because of a preferential action on fast-type, as compared with slow-type, skeletal muscle fibers. It has been shown to have therapeutic benefits for chronic spasticity associated with CNS disorders.

The drug has been reported to improve voiding function in some patients with classic detrusor striated sphincter dyssynergia and was initially reported as being very successful in doing so ([Murdock et al, 1976](#)). Therapy in adults is recommended to begin at a dose of 25 mg daily, and this is gradually increased by increments of 25 mg every 4 to 7 days to a maximal oral dose of 400 mg given in four divided doses. [Hackler and coworkers \(1980\)](#) achieved improvement in voiding function in approximately half of their patients treated with dantrolene but found that such improvement required oral doses of 600 mg daily. Although no inhibitory effect on bladder smooth muscle seems to occur ([Harris and Benson, 1980](#)), the generalized weakness that dantrolene can induce is often significant enough to compromise its therapeutic effects. Other potential side effects include euphoria, dizziness, diarrhea, and hepatotoxicity. Fatal hepatitis has been reported in 0.1% to 0.2% of patients treated with the drug for 60 days or longer, and symptomatic hepatitis may occur in 0.5% of patients on treatment for more than 60 days, whereas chemical abnormalities of liver function are noted in up to 1%. The risk of hepatic injury is twofold greater in female patients ([Ward et al, 1986](#)).

One agreed-on use of dantrolene is to acutely manage malignant hyperthermia, a rare hereditary syndrome characterized by vigorous contraction of skeletal muscle precipitated by excess release of calcium from the sarcoplasmic reticulum, usually in response to neuromuscular blocking agents or inhalational anesthetics. Almost all hospital pharmacies stock parenteral dantrolene for this purpose. Virtually no one currently uses dantrolene for the treatment of voiding dysfunction.

Botulinum Toxin. As mentioned previously, botulinum toxin is an inhibitor of the release of ACh and other transmitters at the neuromuscular junction of somatic nerves in striated muscle, and of autonomic nerves in smooth muscle ([Simpson, 2004](#)). It is interesting that it produces enough weakness of the muscle to prevent or considerably ameliorate spasm or involuntary contraction but not to completely block voluntary control, a phenomenon hypothesized to occur because more active neuromuscular junctions are more likely than less active junctions to be blocked by the effect of the drug ([Hallett, 1999](#)). Its urologic use for the treatment of detrusor striated sphincter dyssynergia was first reported by [Dykstra and colleagues \(Dykstra and Sidi, 1990; Dykstra et al, 1998, 2003\)](#). Injections were carried out weekly for 3 weeks, achieving a duration of effect averaging 2

months. The only side effects reported in the [Dykstra](#) articles were transitory limb paresis and transitory exacerbation of autonomic hyperreflexia.

[Fowler and colleagues \(1992a\)](#) injected 6 women with difficult voiding and urinary retention secondary to what is now called the *Fowler syndrome* (manifesting with abnormal myotonus-like electromyographic activity in the striated urethral sphincter). Although voiding characteristics improved in no patient (a fact attributed to the type of repetitive discharge activity), 3 women did develop transient stress incontinence, a positive effect of sorts, indicating that the sphincter muscle had indeed been weakened. [Petit and colleagues \(1998\)](#) reported on the endoscopic injection of botulinum toxin A (Botox), 150 IU, into the striated urethral sphincter, using a four-point injection technique (the medication was diluted to 4 mL with saline solution). Seventeen patients with SCI or spinal cord disease were treated, and evaluation 1 month after treatment disclosed the following positive results: (1) a decrease in PVR by an average of 176 mL; (2) a decrease in bladder pressure during an emptying contraction by an average of 19 cm H₂O; and (3) a decrease in urethral pressure during an emptying bladder contraction by an average of 24 cm H₂O. The authors judged voiding to be improved in 10 patients. Side effects included the new appearance of stress incontinence in 2 patients and exacerbation of preexisting incontinence in 3. The duration of the effect was variable, but no less than 2 to 3 months. There were no adverse effects on striated muscle elsewhere. The authors concluded that Botox was a promising treatment for striated sphincter dyssynergia in certain patients refractory to CIC or surgery. [Gallien and colleagues \(1998\)](#) injected Botox transperineally in 5 men with traumatic quadriplegia and striated sphincter dyssynergia. Using a total initial dose of 100 U, divided into four injections of 25 U each, the authors noted what they called improved bladder function in all patients, with a significant decrease in residual urine volume (however, on examination of the figures, the mean reduction was only 14 mL, with 1 of the patients requiring a second set of injections). The maximum urethral pressure on average did not change, the maximum detrusor pressure during an emptying episode decreased 5 cm H₂O, and the functional detrusor capacity increased by an average of 89 mL. Urinary catheterization was able to be stopped in 2 patients, and autonomic hyperreflexia dramatically decreased in intensity in 4 patients. The time to improvement was 10 to 21 days and the duration was 3 to 5 months. No patient had significant side effects. [Wheeler and colleagues \(1998\)](#) reported on 3 men with SCI, all of whom had emptying problems related to striated sphincter dyssynergia. The sphincter was injected transperineally with botulinum toxin, using electromyographic control for localization. Two of the patients reported excellent results. [Schurch and colleagues \(1996\)](#) used both transurethral and transperineal injections in 24 male SCI patients with voiding dysfunction secondary to striated sphincter dyssynergia. They judged that in 21 of these patients, striated sphincter dyssynergia was significantly improved with a concomitant decrease in PVR urine volume in "most cases." Nine of 24 patients had a decreased PVR volume from 450 to 50 mL; in 7 patients, the residual urine volumes were less than 50 mL to begin with and remained unchanged; and in 8 patients, the PVR urine volumes were high and remained unchanged. The authors commented that transurethral injections appeared to be more effective, at least in reduction in maximum urethral pressure, than did transperineal injections. They noted no side effects. [de Seze and colleagues \(2002\)](#) performed a double-blind lidocaine-controlled study in 13 patients with spinal cord disease and DSD and demonstrated the superiority of botulinum toxin compared with lidocaine in improving clinical symptoms and increased urethral pressure.

A potential side effect is the spread to nearby muscles, particularly when high volumes of the toxin are injected. Distant effects can also occur, but distant weakness or generalized weakness, caused by the toxins spreading in the blood, is very rare. Botulinum toxin should be used only under close supervision in patients with already disturbed neuromuscular transmission or during treatment with aminoglycosides.

Theoretically, any agent that promotes striated sphincter relaxation in a uroselective manner could be used to decrease outlet resistance and facilitate voiding dysfunction. [Yoshiyama and colleagues \(2000\)](#) described the laboratory use of intravenous α -bungarotoxin as improving voiding in SCI rats. The drug is a toxin

extracted from the venom of a Formosan snake; it selectively blocks nicotinic receptors without influencing transmission in autonomic ganglia. Although a long way from clinical use, nicotinic receptors in the striated sphincter have been shown to be a potential target for drug therapy for striated sphincter dyssynergia.

Conservative Management of Urinary Incontinence: Behavioral and Pelvic Floor Therapy and Urethral and Pelvic Devices

Diane K. Newman, DNP, ANP-BC, FAAN, and Kathryn L. Burgio, PhD

Indications	Bladder Training and Scheduled Voiding Regimens
Assessment before Behavioral Treatments	Behavioral Treatment for Voiding and Pelvic Floor Dysfunction
Patient Education	Lifestyle Modifications
Pelvic Floor Muscle Training	Adherence to Conservative Treatment
Behavioral Training with Urge Suppression	Role of Conservative Interventions for Prevention of Urinary Incontinence
Role of Biofeedback	Mechanical Vaginal and Urethral Devices for Incontinence
Pelvic Floor Muscle Electrical Stimulation	Behavioral Treatment Model for Urology Practice

Conservative treatments for urinary incontinence (UI) include any therapy not involving surgical treatment (Moore et al, 2013). Because behavioral treatments are effective and essentially risk free, they are the mainstay of conservative treatment and are recommended as first-line therapy by several guidelines and consensus panels (Shamliyan et al, 2008; Gormley et al, 2012; Moore et al, 2013). Behavioral treatments are a group of interventions that improve lower urinary tract symptoms (LUTS) by changing patients’ behavior or environment or by teaching new skills.

Behavioral treatment programs usually comprise multiple components, and it is generally recognized that the best programs are individualized according to patient condition, needs, and environment. Components of a behavioral program may include patient education and any of the following: self-monitoring (bladder diary), pelvic floor muscle training (PFMT) and exercise, active use of pelvic floor muscles (PFMs) for urethral occlusion (“stress strategies,” the “knack”), urge prevention and suppression techniques (urge strategies), bladder training with urge control techniques (distraction, self-assertions), biofeedback (BF), electrical stimulation, fixed or incremental voiding schedules, delayed voiding, fluid management, caffeine reduction, dietary changes, weight loss, teaching normal voiding techniques, and/or other lifestyle changes. The most common behavioral interventions are depicted in Figure 80-1, and a list of LUTS to which they are potentially applicable is presented in Box 80-1. In most urologic settings, conservative treatment programs are designed and administered by advanced practice providers (nurse practitioners and physician assistants) (Newman and Wein, 2013; Newman, 2014) after a simple noninvasive assessment.

The most established behavioral treatment programs are PFMT, behavioral training (BT) with urge suppression, and bladder training. These therapies encompass two fundamental approaches to treating LUTS. One approach focuses on the bladder outlet, teaching skills for improving PFM strength and

control and techniques for urge suppression. The other approach focuses on controlling bladder function by changing voiding habits, such as with bladder training and delayed voiding, also supported with urge control techniques. These therapies are grounded in the concept that the patients with LUTS can be educated about their condition and develop skills and strategies to reduce or eliminate symptoms.

Behavioral treatments can also be categorized as patient-dependent or caregiver-dependent (Newman et al, 2014). Bladder training, PFMT, and BT are examples of patient-dependent interventions, because they rely on active patient’s participation. These therapies require adequate function, learning capability, and motivation of the individual. Caregiver-dependent interventions, such as prompted voiding, are useful in people with some functional disabilities. The success of these interventions depends largely on caregiver knowledge and motivation, rather than on the patient’s physical function and mental status.

In addition to these established primary treatment approaches that focus on improving the patient’s direct control over bladder and PFM function, there are a number of lifestyle modifications that seek to improve LUTS indirectly by changing the patient’s behavior or avoiding factors that exacerbate symptoms or make the bladder more difficult to control. These interventions include fluid management, caffeine reduction, reduction of bladder irritants, management of constipation, and weight loss.

Behavioral treatments are supported by a large body of research (Moore et al, 2013) and have been recommended as treatment for UI and non-neurogenic overactive bladder (OAB) by multiple organizations (Shamliyan et al, 2007; Gormley et al, 2012) and international guidelines (Moore et al, 2013). The International Consultation on Incontinence (ICI) Committee on Adult Conservative Management details evidence and recommendations for all conservative treatments (Tables 80-1 and 80-2) using the Oxford grading system (Table 80-3). In this chapter, we also describe devices that can prevent urine loss mechanically.

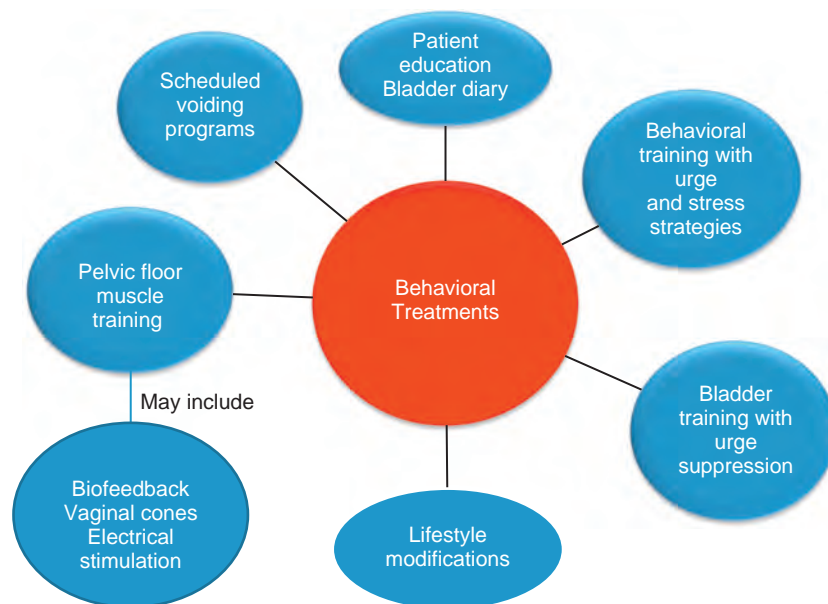

Figure 80-1. Common behavioral treatments. (From Newman DK, Wein AJ. Managing and treating urinary incontinence, 2nd ed. Baltimore: Health Professions Press; 2009.)

TABLE 80-1 Lifestyle Modifications: Levels of Evidence and Recommendations

LIFESTYLE PRACTICE	LEVELS OF EVIDENCE	RECOMMENDATIONS
Diet	Indications from epidemiologic data suggest diet may play a role in UI. Level of evidence: 3	
Fluid	Fluid intake may play a minor role in the pathogenesis of UI.	Minor decrease of fluid intake by 25% may be recommended provided baseline consumption is not <30 mL/kg/day. Grade of recommendation: B
Caffeine	Caffeine consumption may play a role in exacerbating UI. Small clinical trials do suggest that decreasing caffeine intake improves continence. Level of evidence: 2	A reduction in caffeine intake is recommended for those with incontinence symptoms. Grade of recommendation: B
Bowel function	There is some evidence to suggest that chronic straining may be a risk factor for the development of UI. Level of evidence: 3	Further research is needed to define the role of straining during defecation in the pathogenesis of UI.
Obesity	Massive weight loss (15-20 BMI points) significantly decreases UI in morbidly obese women. Level of evidence: 2 Moderate weight loss may be effective in decreasing UI especially if combined with exercise. Level of evidence: 1	Weight loss in obese and morbidly obese should be considered a first-line treatment to reduce UI prevalence. Grade of recommendation: A

BMI, body mass index; UI, urinary incontinence.

Modified from Moore K, Bradley C, Burgio B, et al. Adult conservative treatment. In: Abrams P, Cardozo L, Khoury S, et al, editors. Incontinence. Proceedings from the 5th International Consultation on Incontinence. Plymouth (UK): Health Publications; 2013. p. 1101-228.

TABLE 80-2 Pelvic Floor Muscle Training, Behavioral Therapy, Biofeedback, Electrical Stimulation: Levels of Evidence and Recommendations

TREATMENT	RECOMMENDATIONS
Timed voiding	Timed voiding with a 2-hour voiding interval may be beneficial as a sole intervention for women with mild UI with infrequent voiding patterns. Grade of recommendation: C
PFMT Pregnant women	HPs should carefully consider the cost/benefit of population-based approaches to HP taught antepartum or postpartum PFMT; that is, HP instruction to all pregnant or postpartum women regardless of their current or prior continence status. Grade of recommendation: B Continent, pregnant women having their first baby should be offered a supervised (including regular HP contact) and intensive strengthening antepartum PFMT program to prevent postpartum UI. Grade of recommendation: A
PFMT Postpartum	Postnatal women, immediately after delivery: Individually taught PFMT program that incorporates adherence strategies for women who had a vaginal delivery of a large baby (≥ 4000 g) or a forceps delivery. Grade of recommendation: C For postnatal women with persistent symptoms of UI 3 months after delivery: PFMT should be offered as first-line conservative therapy. Grade of recommendation: A An “intensive” PFMT program (in terms of supervision and exercise content) is likely to increase the treatment effect. Grade of recommendation: B
PFMT	Supervised PFMT should be offered as first-line conservative therapy to women with stress, urgency, or mixed UI. Grade of recommendation: A The most intensive PFMT program possible should be provided (in terms of exercise dose, HP teaching, and supervision) within service constraints; HP taught and supervised programs are better than self-directed programs; more HP contact is better than less. Grade of recommendation: A
PFMT in women with SUI	PFMT is better than electrical stimulation as first-line conservative therapy, particularly if PFMT is intensively supervised. Grade of recommendation: B PFMT is better than BT as first-line conservative therapy. Grade of recommendation: B
PFMT in women with pelvic organ prolapse	PFMT can improve prolapse symptoms and severity. Grade of recommendation: A Preoperative PFMT may help improve quality of life and urinary symptoms in women undergoing surgery for prolapse. Grade of recommendation: C
PFMT in men after prostatectomy	Some preoperative or immediate postoperative instruction in PFMT for men undergoing radical prostatectomy may be helpful. Grade of recommendation: B It is not clear whether PFMT taught by digital rectal examination offers any benefit over and above verbal or written instruction in PFMT. Grade of recommendation: B The use of BF to assist PFMT is currently a therapist/patient decision based on economics and preference. Grade of recommendation: B
PFMT + BT in women with UI or MUI	PFMT and BT are effective first-line conservative therapy. Grade of recommendation: B For women with SUI or MUI, a combination of PFMT/BT may be better than BT alone in the short term. Grade of recommendation: C

Continued

TABLE 80-2 Pelvic Floor Muscle Training, Behavioral Therapy, Biofeedback, Electrical Stimulation: Levels of Evidence and Recommendations—cont'd

TREATMENT	RECOMMENDATIONS
BT	<p>BT is an appropriate first-line treatment for UI in women.</p> <p>Grade of recommendation: A</p> <p>In a choice between BT and anticholinergic drug for women with DO or UUI, either may be effective.</p> <p>Grade of recommendation: B</p> <p>BT may be preferred by some clinicians and women because it does not produce the side effects and adverse events associated with drug therapy.</p> <p>Grade of recommendation: D</p> <p>There may be no benefit in adding brief written instruction in BT to drug therapy for incontinence, but it may improve episodes of frequency.</p> <p>Grade of recommendation: B</p> <p>A combination of PFMT/BT may be better than PFMT alone in the short-term for women with symptoms of stress UI or MUI.</p> <p>Grade of recommendation: B</p> <p>Clinicians and researchers should refer to the operant conditioning and educational literature to provide a rationale for their choice of training parameters or approach.</p> <p>Grade of recommendation: D</p> <p>HPs should provide the most intensive BT supervision that is possible within service constraints.</p> <p>Grade of recommendation: D</p>
PFMES	<p>PFMES might be better than no treatment in improving symptoms.</p> <p>Grade of recommendation: B</p> <p>For women with SUI, maximal clinic-based PFMES might be better than daily low-intensity home-based PFMES in improving symptoms.</p> <p>Grade of recommendation: B</p> <p>PFMES plus PFMT or BF-assisted PFMT program does not appear to add benefit.</p> <p>Grade of recommendation: B</p> <p>For men with postprostatectomy incontinence, there does not appear to be any benefit of adding PFMES to a PFMT program</p> <p>Grade of recommendation: B</p>
Vaginal cones	<p>For women with SUI, VCs with supervised training sessions by a trained HP can be offered as a first-line conservative therapy to those who can and are prepared to use them.</p> <p>Grade of recommendation: B</p> <p>VCs may be inappropriate in some cases because of inability to insert or retain the cone or because of side effects and discomfort. Trained HP assessment is recommended</p> <p>Grade of recommendation: D</p>

BF, biofeedback; BT, behavioral therapy; DO, detrusor overactivity; HP, health professional; MUI, mixed urinary incontinence; PFMES, pelvic floor muscle electrical stimulation; PFMT, pelvic floor muscle training; SUI, stress urinary incontinence; UI, urinary incontinence; UUI, urge urinary incontinence; VC, vaginal cone.

Modified from Moore K, Bradley C, Burgio B, et al. Adult conservative treatment. In: Abrams P, Cardozo L, Khoury S, et al, editors. Incontinence. Proceedings from the 5th International Consultation on Incontinence. Plymouth (UK): Health Publications; 2013. p. 1101–228.

BOX 80-1 Conditions That Have Benefited from Behavioral Treatments

- Stress urinary incontinence
- Overactive bladder (urgency, frequency)
- Urgency urinary incontinence
- Neurogenic detrusor overactivity
- Mixed urinary incontinence
- Nocturia
- Pelvic floor muscle spasm (dysfunction)
- Nonrelaxing striated sphincter

Modified from Newman DK, Wein AJ. Office-based behavioral therapy for management of incontinence and other pelvic disorders. Urol Clin North Am 2013;40:613–35; and Newman DK, Wein AJ. Managing and treating urinary incontinence, 2nd ed. Baltimore: Health Professions Press; 2009. p. 245–306.

INDICATIONS

Behavioral interventions are well established for treating stress and urgency UI and OAB. Behavioral interventions are also appropriate for voiding dysfunction, although less evidence exists for this condition. Most patients who are motivated and cooperative with behavioral treatment experience some degree of improvement. There is wide variation in outcomes, and little is known of the characteristics of patients who respond best to behavioral treatment. **Therefore, because they are virtually risk free, behavioral treatments should be offered as first-line therapy to any man or woman who is willing and able to participate.** Even patients with dementia can benefit from the appropriate, caregiver-guided behavioral treatment program.

ASSESSMENT BEFORE BEHAVIORAL TREATMENTS

Perhaps the most important step in evaluating the patient with LUTS is a **focused and detailed history**, including onset of

TABLE 80-3 Oxford Levels of Evidence and Grades of Recommendation

Any level of evidence may be positive (the therapy works) or negative (the therapy does not work). A level of evidence is given to each individual study.	
LEVEL	EVIDENCE
1	Usually involves meta-analysis of trials (RCTs) or a good-quality RCT, or “all or none” studies in which no treatment is not an option—for example, in vesicovaginal fistula.
2	Includes “low”-quality RCT (e.g., <80% follow-up) or meta-analysis (with homogeneity) of good-quality prospective “cohort studies.” These may include a single group when individuals who develop the condition are compared with others from within the original cohort group. There can be parallel cohorts, in which those with the condition in the first group are compared with those in the second group.
3	Includes: <ul style="list-style-type: none"> • Good quality retrospective “case-control studies” in which a group of patients who have a condition are matched appropriately (e.g., for age, sex, etc.) with control individuals who do not have the condition. • Good quality “case series” in which complete group of patients, all with the same condition/disease/therapeutic intervention, are described, without a comparison control group.
4	Includes expert opinion where the opinion is based not on evidence but on “first principles” (e.g., physiologic or anatomic) or bench research. The Delphi process can be used to give “expert opinion” greater authority. In the Delphi process a series of questions are posed to a panel; the answers are collected into a series of “options”; the options are serially ranked; if a 75% agreement is reached then a Delphi consensus statement can be made.
Uses four grades from the Oxford system. As with the levels of evidence the grades of evidence may apply either positively (do the procedure) or negatively (do not do the procedure).	
GRADE	RECOMMENDATION
A	Usually depends on consistent level 1 evidence and often means that the recommendation is effectively mandatory and placed within a clinical care pathway. However, there will be occasions in which excellent evidence (level 1) does not lead to a grade A recommendation—for example, if therapy is prohibitively expensive, dangerous, or unethical. Grade A recommendation can follow from level 2 evidence. However, a grade A recommendation needs a greater body of evidence if based on anything except level 1 evidence.
B	Usually depends on consistent level 2 and/or 3 studies, or “majority evidence” from RCTs.
C	Usually depends on level 4 studies or “majority evidence” from level 2 or 3 studies or Delphi-processed expert opinion.
D	“No recommendation possible” would be used where the evidence is inadequate or conflicting and when expert opinion is delivered without a formal analytical process, such as by Delphi.

RCT, randomized controlled trial.

From Abrams P, Khoury S, Grant A. Evidence based medicine: overview of the main steps for developing and grading guideline recommendation. In: Abrams P, Cardozo L, Khoury S, et al, editors. Incontinence. Paris: EAU/ICUD; 2013. p. 8–9.

symptoms, duration, progression, characteristics, and situational antecedents or triggers (Newman, 2005; Newman and Wein, 2013). Understanding these factors will determine the design of a behavioral treatment program and guide its implementation.

To supplement the history, it is very useful for the patient to complete a 3- to 7-day bladder diary (Tincello et al, 2007) (see Fig. 80-2 for an example of a completed bladder diary with voided volumes, sometimes referred to as a Frequency Volume Chart). The diary is a valuable tool for the patient, as well as the provider. In the assessment phase, the diary provides information on the type and amount of fluid intake, type and frequency of symptoms, such as incontinence episodes, frequency of urination, the urgency associated with each, and the circumstances or reasons for incontinence episodes, which helps the provider plan appropriate components of behavioral intervention (Sampselle, 2003). Many providers also are interested in having the patient note the type and quantity of absorbent incontinence pads used and to quantify amount of urine leakage.

A bladder diary is also the best noninvasive tool available to objectively monitor the patient's voiding habits and the effect of treatment on symptoms, guiding the use of various treatment components. In bladder training programs, having patients record the times they void provides a foundation for determining initial and incremental voiding intervals. Voided volumes are more bur-

densome for patients to document, but they provide a practical estimate of the patient's functional bladder capacity in daily life.

In addition to guiding behavioral treatment from the provider's perspective, the self-monitoring effect of completing a diary can enhance the patient's awareness of drinking and voiding habits and helps them recognize how their LUTS, especially incontinent episodes, may be related to their activities. This increased awareness is thought to empower the patient to help in retraining more effectively (Vella et al, 2012). A review of a diary can assist patients in identifying the times they are at increased risk for a UI episode and activities that precipitate UI episodes, which helps them be prepared to implement behavioral skills.

Another approach to collecting information on bladder habits is the Questionnaire-Based Voiding Diary (QVD) for self-assessment of the type and volume of fluid intake and the type of UI (Arya et al, 2008) (Fig. 80-3). This instrument has been validated and can be completed in an initial office visit in 5 to 7 minutes (Arya et al, 2008, 2011).

In addition to a bladder diary, a urinalysis performed by dipstick or microscopic examination is recommended to check for signs of infection. A postvoid residual value is not necessary before instituting behavioral treatment, unless symptoms suggest incomplete bladder emptying.

BLADDER DIARY					
DAY 1					
Time 	Trips to bathroom How much urine did you pass (in oz)?	Did you feel a strong urge to go? (yes, no)	Urine Leakage	Circumstances of Urine Leakage	Drinks What kind and how much? 1 glass = 4 oz 1 cup = 8 oz

QUESTIONNAIRE-BASED VOIDING DIARY (QVD)

Instructions: We would like to find out about your fluid intake, urinary output and urinary symptoms. Please answer each question, thinking about your fluid consumption and the symptoms you have experienced in the last month.

A. Please fill in the bubble for the number of drinks AND the amount for each beverage. If you do not drink a certain type of beverage daily , please fill in the bubble corresponding to 0.													
Beverage	Number of drinks per day (If 1 or more drinks per day, please indicate drink size →)											Size of each drink	
A1. Water	<input type="radio"/> 0	<input type="radio"/> 1	<input type="radio"/> 2	<input type="radio"/> 3	<input type="radio"/> 4	<input type="radio"/> 5	<input type="radio"/> 6	<input type="radio"/> 7	<input type="radio"/> 8	<input type="radio"/> 9	<input type="radio"/> 10	<input type="radio"/> 10+	<input type="radio"/> Less than 8 oz <input type="radio"/> 8-16 oz <input type="radio"/> 17-24 oz <input type="radio"/> More than 24 oz
A2. Caffeinated Coffee	<input type="radio"/> 0	<input type="radio"/> 1	<input type="radio"/> 2	<input type="radio"/> 3	<input type="radio"/> 4	<input type="radio"/> 5	<input type="radio"/> 6	<input type="radio"/> 7	<input type="radio"/> 8	<input type="radio"/> 9	<input type="radio"/> 10	<input type="radio"/> 10+	<input type="radio"/> Less than 8 oz <input type="radio"/> 8-16 oz <input type="radio"/> 17-24 oz <input type="radio"/> More than 24 oz
A3. Decaffeinated Coffee	<input type="radio"/> 0	<input type="radio"/> 1	<input type="radio"/> 2	<input type="radio"/> 3	<input type="radio"/> 4	<input type="radio"/> 5	<input type="radio"/> 6	<input type="radio"/> 7	<input type="radio"/> 8	<input type="radio"/> 9	<input type="radio"/> 10	<input type="radio"/> 10+	<input type="radio"/> Less than 8 oz <input type="radio"/> 8-16 oz <input type="radio"/> 17-24 oz <input type="radio"/> More than 24 oz
A4. Caffeinated Tea	<input type="radio"/> 0	<input type="radio"/> 1	<input type="radio"/> 2	<input type="radio"/> 3	<input type="radio"/> 4	<input type="radio"/> 5	<input type="radio"/> 6	<input type="radio"/> 7	<input type="radio"/> 8	<input type="radio"/> 9	<input type="radio"/> 10	<input type="radio"/> 10+	<input type="radio"/> Less than 8 oz <input type="radio"/> 8-16 oz <input type="radio"/> 17-24 oz <input type="radio"/> More than 24 oz

QUESTIONNAIRE-BASED VOIDING DIARY (QVD)

C. Urinary output	Never	Occasionally	Sometimes	Most of the time	All of the time
C1. Do you urinate large amounts of urine when you first wake up in the morning?	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>
C2. Do you urinate large amounts of urine in the afternoon (12 noon to 5 pm)?	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>
C3. Do you urinate large amounts of urine in the evening (5 pm to bedtime)?	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>
C4. Do you urinate large amounts of urine in the night after you have fallen asleep?	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>

D. Urinary symptoms

- D1. How often do you urinate in the daytime?
- ☐ 1-5
 - ☐ 6-10
 - ☐ 11-15
 - ☐ 16-20
 - ☐ more than 20 times
- D2. How often do you have to get up in the night to urinate after you have fallen asleep?
- ☐ Never
 - ☐ 1
 - ☐ 2
 - ☐ 3
 - ☐ 4 or more
- D3. Do you have to rush to the toilet to urinate?
- ☐ Never
 - ☐ Occasionally
 - ☐ Sometimes
 - ☐ Most of the time
 - ☐ All of the time
- D4. Do you leak urine (even small drops) as you are rushing to the toilet?
- ☐ Never
 - ☐ Occasionally
 - ☐ Sometimes
 - ☐ Most of the time
 - ☐ All of the time
- D5. Do you leak urine when you cough or sneeze or are physically active?
- ☐ Never
 - ☐ Occasionally
 - ☐ Sometimes
 - ☐ Most of the time
 - ☐ All of the time
- D6a. How often do you experience urinary leakage?
- ☐ Less than once a month
 - ☐ A few times a month
 - ☐ A few times a week
 - ☐ Every day and/or night
- D6b. How much urine do you lose each time?
- ☐ Drops
 - ☐ Small splashes
 - ☐ More

Severity Index. This will be completed by your doctor or nurse.

☐ Slight, ☐ Moderate, ☐ Severe, ☐ Very Severe

Arya LA, Banks C, Gopal M, et al. Development and testing of a new instrument to measure fluid intake, output, and urinary symptoms: the questionnaire-based voiding diary. *Am J Obstet Gynecol* 2008;198:559.e1-559.e7.

PATIENT EDUCATION

Because behavioral treatments are based on principles of learning, an important first step in any behavioral program is to provide basic education, so that patients can understand their condition, the treatment process, and the therapeutic goals. Patient education includes an explanation of the anatomy of the bladder, urethra, vagina/prostate, pelvic floor, and rectum; how they function and are interrelated; and the causes and mechanisms of their particular condition. **It is essential for patients to understand that a behavioral program is based on changing habits and learning new skills, and that improvement is often gradual (Lukacz et al, 2011).** Further, understanding that their results will depend on active participation and daily practice facilitates adherence and realistic expectations about therapeutic outcomes.

PELVIC FLOOR MUSCLE TRAINING

PFMT and exercise, also known as pelvic floor rehabilitation (Payne, 2012), is a cornerstone of behavioral treatment for LUTS. First described by Margaret Morris in 1936, it was originally designed to teach patients how to control and exercise perivaginal muscles with the goal of strengthening the muscles and reducing stress UI. It was first popularized by Arnold Kegel, a gynecologist who proposed that stress UI was due to a lack of awareness of function and coordination of PFMs (Kegel, 1948) and who also demonstrated that women could reduce their stress UI through PFMT and exercise (Kegel, 1948, 1956). Over time, this intervention has evolved both as a nurse-directed behavior treatment and as a physical therapy, combining principles from both fields into a widely accepted conservative treatment for incontinence and other LUTS.

In women, it is postulated that a PFM contraction may raise the urethra and press it toward the symphysis pubis, prevent urethral descent, and improve structural support of the pelvic organs (Berghmans et al, 1998). PFMT may result in hypertrophy of the striated muscles, thus increasing the external mechanical pressure on the urethra. Intensive PFMT is also hypothesized to reinforce structural support of the bladder neck in women, limiting its downward movement during increases in abdominal pressure (DeLancey, 1988; Bø, 1995, 2004).

PFMT involves the patient learning how to contract and relax the PFM, performing a regular exercise regimen to improve strength and control and actively using a PFM contraction to occlude the urethra during physical activities that increase abdominal pressure and precipitate urine leakage (Miller et al, 1998). Details of training regimens vary, and few are well-described in the current evidence-based literature (Moore et al, 2013).

Assessment of Pelvic Floor Muscle Function

Before initiation of PFMT, an assessment of the PFM can provide useful baseline information about strength, coordination, and control. PFM function can be assessed by several methods, including digital palpation, visual observation, electromyography (EMG), manometry, or ultrasonography. Digital assessment is the most commonly used technique in clinical practice (Newman and Wein, 2009, 2013). The most widely used digital palpation methods are the Brink score and the Laycock PERFECT assessment scheme (Newman and Laycock, 2008). The Brink score employs a 4-point scale to assess the contraction pressure, vertical displacement, and endurance of squeeze. The Laycock PERFECT (mnemonic for: Power, Endurance, Repetitions, Fast, Every, Contraction, Timed) assessment scheme uses a 6-point scale to score strength and endurance and the number of repetitions and fast contractions.

PFM strength can be determined in women by inserting one or two fingers into the vagina to the level of the first knuckle, then palpating the muscular attachments along the pubic arch and the insertion of the levator ani and coccygeus muscles (Newman and Laycock, 2008; Newman, 2014). The levator ani can be palpated just superior to the hymeneal ring, at the 4- and 8-o'clock positions,

to determine strength, and whether palpation reproduces any discomfort or tenderness. The patient is asked to contract the PFMs around the examiner's finger with as much force and for as long as she is able. She is asked to squeeze or pull in and upward with vaginal muscles in short, fast contractions called "flicks." **It is important to realize that, when asked to contract the PFM, women may use the wrong muscles, strain down, or perform a Valsalva maneuver, or fail to activate all layers of the pelvic musculature.** The examiner notes through observation whether accessory muscles (such as gluteal, abdominal muscles) also contract.

When assessing PFM strength, three criteria should be used (Brink et al, 1989) and the results noted (Messelink et al, 2005):

- Pressure: The amount of pressure or strength of the muscle contraction, which can range from imperceptible to a firm squeeze
- Duration: The number of seconds that the examiner feels the muscle contraction
- Alteration in position: In a well-supported pelvic floor, the muscle contraction can lift the base of the examiner's finger. Use of accessory muscles should be noted (abdominal movement, gluteal lifting). If the patient has an "overactive PFM" (voluntary PFM relaxation is absent, partial or complete), the degree should be noted. Overactive PFM is defined as one that does not relax or may even contract when relaxation is functionally needed (e.g., during micturition).

Assessment of the PFM in men and women also can be performed by evaluating anal sphincter contraction and tone. This is done by having the patient relax and bear down. As the sphincter relaxes, the examiner gently inserts an index finger into the anal canal in a direction pointing toward the umbilicus. Resting sphincter tone can be noted as weak, moderate, or strong. Normally, the muscles of the anal sphincter close snugly around the entire circumference of the examiner's finger. In the rectum, the distal external sphincter is felt just inside the anal canal. The puborectalis portion of the levator ani muscle can be palpated approximately 2.5 to 4 centimeters from the anal verge. To assess the strength of the sphincter muscle, the patient is asked to tighten the rectum. The examiner should feel a gripping or "pulling in" around the entire finger circumference.

Teaching Pelvic Floor Muscle Control

- The first step in PFMT is to teach the patient how to identify the PFMs and contract and relax them reliably. This can be done using verbal feedback based on vaginal or anal palpation during the digital assessment. It can also be done using visual or auditory BF or electrical stimulation (Newman and Wein, 2009, 2013; Newman, 2014). Instructions to patients can include the following:
 - "Contract your muscles around my finger(s). Try to pull up and in."
 - "Without tensing the muscles of your legs, buttocks, or stomach, imagine trying to prevent the passing of gas or pinching off of a stool by tightening the ring of muscles around the anus. A closing and lifting sensation should be felt."
 - For men: "Imagine moving the penis up and down without moving any other part of the body."
 - For women: "You should feel your vagina and rectum pull up and in."

One problem commonly encountered in teaching PFM control is that patients tend to recruit other muscles, such as the rectus abdominis muscles or gluteal muscles, instead of or in addition to the PFMs. Contracting certain abdominal muscles can be counterproductive when it increases pressure on the bladder or pelvic floor. **Thus it is important to observe for the use of other muscles and help patients contract PFMs selectively while relaxing ancillary muscles.** Instructing patients not to hold their breath or to count out loud can be helpful to avoid bearing down. Coordinated training of transversus abdominis muscles also has been recommended by some clinicians, because it is thought that these muscles facilitate

PFM contraction. However, in a review of the literature, [Bo and colleagues \(2009\)](#) noted an absence of evidence for this type of training, and it remains controversial.

It is important to verify that patients have identified and can contract the PFMs properly before initiating an exercise regimen. Not being able to identify the PFMs or to exercise them incorrectly may be the most common reason for poor outcomes with this treatment modality. PFM control is a skill that may take time to master, but with repeated training, most patients are successful. In the past, most patients were given a pamphlet or brief verbal instructions on how to do PFM exercises and were told to “lift the pelvic floor” or to interrupt the urinary stream. Although these simple approaches may be adequate for some patients, it does not ensure that they understand which muscles to use when they begin a structured exercise program at home.

Pelvic Floor Muscle Exercise Regimens

Once patients demonstrate the ability to properly contract and relax the PFM, they are given instructions for daily practice and exercise. The purpose of daily exercise is twofold: to increase muscle strength and to enhance motor skills through practice. Specific exercise regimens vary considerably in frequency and intensity, and the ideal exercise regimen has not yet been determined. However, good results have been achieved in several trials using 45 to 60 paired contractions and relaxations per day.

We use an “exercise prescription” to prescribe the daily exercise program (sample of an exercise prescription is found in [Box 80-2](#)) ([Newman and Wein, 2013](#); [Newman, 2014](#)). One approach is to recommend a series of “quick flicks” or 1- to 2-second contractions, followed by sustained contractions (endurance contractions) of 5 seconds or longer. The patient is encouraged to aim for a high level of concentrated effort with each PFM contraction because greater contraction intensity is associated with improvement in PFM strength.

It is equally important to relax the PFM completely between each contraction. Each exercise consists of muscle contraction followed by a period of relaxation using a 1:1 or 1:2 ratio. This allows the muscles to recover between contractions and facilitates optimal strength building.

It is usually recommended that patients space the exercises across the day, typically in 2 to 5 sessions per day to avoid muscle fatigue. Exercising while in the prone position is often recommended at first, because it is the least challenging. However, it is important for patients to progress to sitting or standing positions with time, so that they become comfortable and skilled using their muscles to avoid incontinence in any position.

Use of Pelvic Floor Muscle Contraction to Prevent Stress Incontinence

The goal of behavioral treatment for stress UI is to teach patients how to prevent urine loss in daily life by occluding the urethra using active contraction of PFMs ([Miller et al, 1998](#)). Although exercise alone can improve urethral pressure and structural support and reduce incontinence, this motor skill enables patients to consciously occlude the urethra at specific times when urine loss is imminent. A careful history or examination of a bladder diary can alert the provider and patient of the circumstances during which each individual patient commonly experiences urine loss. Patients then learn to anticipate these activities and prevent leakage by contracting the PFM to occlude the urethra before and during coughing, sneezing, lifting, or any other physical activities that have precipitated urine leakage.

This skill has been referred to as the “stress strategy” ([Burgio et al, 1989](#)) and “the Knack” ([Miller et al, 1996, 2008](#)). Although using this technique requires initial vigilance on the part of the patient and a conscious effort to develop the habit of using muscles to increase urethral closure, it eventually becomes automatic. A handout with instructions for the patient is presented in [Box 80-3](#).

BOX 80-2 Sample Pelvic Floor Muscle Exercise Prescription

Please complete the following exercises every day:

SHORT QUICK EXERCISE

Contract the muscle quickly for 1 to 2 seconds and immediately relax.

LONG SUSTAINED EXERCISE

Contract the muscle, and hold the contraction for a count of ____ then immediately relax for a count of ____.

After each muscle contraction, be sure to rest your muscle for the same amount of time.

When you have completed the short quick exercise and the long sustained exercise in the lying down, sitting, and standing positions, you will have completed one session.

EXERCISE SESSION

Lying Down

Short quick exercise: Do 5 exercises holding for 1 to 2 seconds.
Long sustained exercise: Do 5 exercises holding for (5 to 10) seconds.

Sitting

Short quick exercise: Do 5 exercises holding for 1 to 2 seconds.
Long sustained exercise: Do 5 exercises holding for (5 to 10) seconds.

Standing

Short quick exercise: Do 5 exercises holding for 1 to 2 seconds.
Long sustained exercise: Do 5 exercises holding for (5 to 10) seconds.

Do two exercise sessions each day—one in the morning and one in the evening, for a total of 60 exercises.

Special Tips

- Always empty your bladder before beginning your exercise session.
- Count out loud with sustained or long exercises; remember to keep breathing!
- Keep your stomach, leg, and buttock muscles relaxed. Rest your hand on your stomach; it should not move or tense.
- If it helps, take a deep breath between each exercise to help you keep other muscles relaxed.

Modified from Newman DK, Wein AJ. Office-based behavioral therapy for management of incontinence and other pelvic disorders. *Urol Clin North Am* 2013;40:613–35; and Newman DK, Wein AJ. Managing and treating urinary incontinence, 2nd ed. Baltimore: Health Professions Press; 2009. p. 245–306.

Evidence for Pelvic Floor Muscle Training

PFMT is an established treatment supported by a large body of evidence. A Cochrane review of PFMT-based treatments concluded that these treatments were effective for both stress and mixed UI ([Dumoulin et al, 2014](#)) and can reduce urgency, but women with pure stress UI may have better outcomes ([Bo & Herbert, 2013](#)). PFMT is better than no treatment, a placebo drug, or an inactive control treatment for women with stress, urgency, and mixed UI ([Ayeleke et al, 2013](#); [Moore et al, 2013](#)). Women treated with PFMT show benefit on a number of outcomes, including cure, better quality of life, reduction in daily leakage episodes, and less urine

BOX 80-3 Handout for Teaching Stress Strategies and the “Knack”

Urine leakage occurs when the pressure pushing urine out is higher than the pressure holding it in your bladder. Any activity that increases pressure in your stomach may cause you to lose urine. Leakage can occur during coughing, sneezing, standing up, when exercising, bending, or lifting. It is possible to squeeze your pelvic floor muscles during specific activities and prevent leakage. A bladder diary will help you identify activities that cause leakage.

1. Quickly squeeze your pelvic floor muscles (like trying to hold back gas) just before and during activities that normally cause you to leak (coughing, sneezing, bending, lifting, getting up from a chair).
2. If you forget to squeeze your muscles and urine leaks out, go ahead and squeeze your muscles right then. It will not prevent that leakage, but will help link squeezing the muscles with that activity.
3. The Stress Strategy requires careful timing and practice. It may take some time for you to get the “knack” of doing it. Do not get discouraged. Eventually, it will become automatic.
4. Remember: **“Squeeze before you sneeze.”**

Modified from Burgio KL, Pearce KL, Lucco AJ. *Staying dry: a practical guide to bladder control*. Baltimore: Johns Hopkins Press; 1989. p. 67–100; and Newman DK, Wein AJ. *Managing and treating urinary incontinence*, 2nd ed. Baltimore: Health Professions Press; 2009. p. 245–306.

leakage on a pad or paper towel test immediately after treatment and long term. Cure rates for PFMT range from 16% to 27% and improvement rates from 48% to 80.7%. Evidence is lacking regarding the best approach to PFMT, but **there is consensus that supervised PFMT is more effective than unsupervised programs** (Hay-Smith et al, 2011, 2012; Moore et al, 2013), although the degree and type of supervision needed are uncertain. Moreover, the treatment effect appears to be enhanced when PFMT is based on sound muscle training principles such as specificity, overload progression, correct contraction confirmed before training, and use of the “knack” (intentional muscle contraction), a motor skill for PFM contraction.

The effect of PFMT in women with stress UI does not seem to decrease with age; in trials of older women, both primary and secondary outcome measures were comparable to those in trials focused on younger women. Thus age should not be a deterrent to PFMT (Betschart et al, 2013). Based on this evidence, supervised PFMT should be offered as a first-line conservative therapy for women of all ages with stress, urgency, or mixed UI.

Postpartum Urinary Incontinence

PFMT is recommended during pregnancy and after childbirth, both for prevention and treatment of incontinence (Neilson, 2009; Mørkved and Bø, 2013; Wesnes and Lose, 2013). Cochrane reviews of randomized or quasi-randomized controlled trials in pregnant or postnatal women included 22 trials involving 8485 women (Boyle, 2012, 2014). Postpartum women with UI who were randomized to PFMT taught and supervised by a health care professional were less likely to be incontinent 6 to 12 months after delivery, compared to no treatment or usual care. The ICI committee (Moore et al, 2013) recommends that PFMT should be offered as first-line therapy to postpartum women with UI persisting 3 months after delivery. Evidence for the value of perinatal PFMT for prevention of postpartum UI can be found in the section Role of Conservative Interventions for Prevention of Urinary Incontinence.

Figure 80-4. Example of weighted vaginal weights.

Postprostatectomy Urinary Incontinence

Stress UI is a complication of radical prostatectomy, regardless of the technique used (Resnick et al, 2013). PFMT is the primary conservative treatment for UI secondary to prostatectomy. It may be taught using digital rectal examination (DRE) with verbal feedback or with BF or electrical stimulation.

Trials of PFMT for established postprostatectomy UI have yielded mixed results but generally show that PFMT reduces UI in the first 3 months after surgery (Campbell et al, 2012; Moore et al, 2013). Less research has focused on UI that persists long term. One randomized controlled trial (RCT) compared BT (PFMT + bladder control strategies) versus no treatment in men with UI persisting 1 to 17 years after radical prostatectomy (Goode et al, 2011). After 8 weeks of treatment, men in the BT group showed 55% reduction in UI episodes, significantly greater than the 24% reduction in the control group, and improvements were sustained to 12 months.

According to Moore and colleagues (2013), it is not clear whether PFMT should be delivered in the form of hands-on therapy or verbal instruction. Current evidence suggests that the addition of PFM electrical stimulation or BF does not appear to improve continence outcomes over PFMT alone (Mariotti et al, 2009). However, BF is an effective approach and providers may prefer it over DRE.

Many studies of postprostatectomy UI involve perioperative PFMT for prevention of postprostatectomy UI. These studies are covered in the section on Role of Conservative Interventions for Prevention of Urinary Incontinence.

Vaginal Cones for Pelvic Floor Muscle Training

Weighted vaginal cones are sometimes used to help women identify and control their PFMs and to support adherence to PFMT (Herbison and Dean, 2013; Moore et al, 2013) (see Fig. 80-4 for an example of a set of graded weighted vaginal cones). When a cone is placed in the vagina while standing, it is usually necessary to contract the PFM to keep it from slipping out. The sensation of losing the cone prompts women to hold it in by tightening the PFMs. Women are instructed to insert the heaviest cone they can retain while standing, at first, and then while walking around. When successful with this first cone, they are progressed to the next heaviest cone. The goal is for women to be able to retain the cone using a PFM contraction while walking around for two sessions of 15 min/day, for 1 month or more. Some women find the cones helpful and motivating. Others find them uncomfortable, difficult to insert (because of a narrowed vaginal opening), or impossible to retain (because of a prolapse or enlarged vaginal opening).

A 2013 Cochrane review (Herbison and Dean, 2013) analyzed 23 trials involving 1806 women, of whom 717 received cones. All of the trials were small, and in many the quality was difficult to

judge. They concluded that there was some evidence that weighted vaginal cones are better than no active treatment in women with stress UI and may be of similar effectiveness to PFMT and pelvic floor electrical stimulation, but more definitive trials are needed to understand the role of weighted vaginal cones in the treatment of UI.

BEHAVIORAL TRAINING WITH URGE SUPPRESSION

BT is a stand-alone treatment that teaches patients how to use their PFMs to inhibit detrusor contraction and how to use this skill as a part of a larger urge suppression strategy that constitutes a new way of responding to urge for patients with urgency, frequency, and/or urgency UI. BT evolved out of BF-assisted BT in which bladder and anal sphincter BF were used together to teach patients to inhibit detrusor contraction during retrograde bladder filling. Originally, the focus of training was on bladder pressure feedback and learning cortical inhibition of detrusor contraction. During these BF sessions, it was observed that spontaneous anal sphincter activity appeared to affect detrusor pressures, and it was subsequently demonstrated that a well-timed, volitional contraction of the anal sphincter (reflecting PFM), guided by visual BF, could abort fully developed detrusor contractions, deter developing contractions, and suppress the sensation of urgency (Burgio et al, 1985, 1998).

Later, it was shown that this skill could be taught without BF, using verbal feedback based on vaginal palpation instead. In a randomized trial of BT with and without BF, older women with urgency UI, taught using verbal feedback based on vaginal palpation, achieved outcomes as good as those achieved using bladder-sphincter BF when this skill was integrated into a larger strategy (Burgio et al, 2002). BT is now generally conducted using verbal feedback based on vaginal palpation, making it more widely available.

Based on these findings, although PFMT and exercise was originally designed for the treatment of stress UI, it is now used as a central element in the treatment of urgency UI and OAB. In BT, patients are taught PFM control and exercise in the same way as for stress UI. What differs is how they use their muscles to manage urgency and prevent urine loss. In addition to using PFM to occlude the urethra, patients learn to use PFM contractions as one part of a broader strategy to respond to the sensation of urge, as follows.

Patients with urgency and urgency UI often feel compelled to rush to the nearest bathroom when they feel the urge to void, believing that they are about to lose control. With BT, they learn how this natural “gotta go” response is actually counterproductive, because it increases physical pressure on the bladder, increases the feeling of fullness, exacerbates urgency, and triggers detrusor contraction. Further, as the patient approaches the toilet, visual cues can trigger urgency and incontinence. To avoid this conditioned response, patients are taught not to rush to the bathroom when they feel the urge to void. Instead, they are advised to stay away from the bathroom, so as to avoid exposure to cues that trigger urgency. They are encouraged to pause, sit down if possible, relax the entire body, and contract PFM repeatedly, without relaxing in between contractions, to diminish urgency, inhibit detrusor contraction, and prevent urine loss. They focus on inhibiting the urge sensation, giving it time to pass. Once the sensation subsides, they walk at a normal pace to the toilet. (A handout for teaching the urge suppression strategy is in Fig. 80-5.)

Once patients master the urge suppression strategy, instead of walking to the bathroom immediately after suppressing the urge, they are encouraged to delay voiding for 5 minutes to consolidate their skill. If they are voiding too frequently, this delayed voiding interval can be increased gradually until they achieve a normal voiding frequency.

The effectiveness of BT with urge suppression as a stand-alone therapy for urgency UI has been established in several clinical series studies (Burgio et al, 1985; Baigis-Smith et al, 1989; Rose et al, 1990; McDowell et al, 1992) and in RCTs using intention-to-treat models, in which mean reductions of incontinence range from

When the urge strikes...

- Stop and stay still. **Do not** rush to the toilet.
- Sit down if you can.
- Squeeze your pelvic floor muscles quickly 3 to 5 times and repeat as needed—don't relax muscles in between.
- Relax the rest of your body. Taking several slow, deep breaths.
- Concentrate on suppressing the urgency. Once it calms down, squeeze again as you stand.
- Walk to the bathroom at a normal pace—do not rush or hurry.
- If the urge returns on the way to the bathroom, stop and squeeze away the urge again.

WHEN TO VOID

Here are some other ways you can try to control your bladder urge.

- **Distract yourself** by focusing on a mental activity: Use mind games. Turn your attention to counting backward from 100 by 7s or working on a crossword puzzle. Do a task that requires a lot of thought—for example, balance your checkbook, write a letter, do homework, or some other activity that requires a great deal of attention.
- **Use self-talk or good self-statements.** Tell yourself: “I am the boss, not my bladder.” “I am in control.” “I can beat this.” Create a statement that fits your situation and personality the best. Keep saying this statement over and over until the feeling of urgency passes.

Figure 80-5. Patient handout with instructions for the urge suppression strategy. (Urge wave, from Burgio KL, Pearce KL, Lucco AJ. *Staying dry: a practical guide to bladder control*. Baltimore: Johns Hopkins Press; 1989. p. 79; When to void, from Burgio KL, Pearce KL, Lucco AJ. *Staying dry: a practical guide to bladder control*. Baltimore: Johns Hopkins Press; 1989. p. 80; Steps to controlling urgency, courtesy Diane K. Newman.)

60% to 80% (Burgio et al, 1998, 2002). In one RCT, BT reduced incontinence episodes significantly more than individually titrated drug treatment and patient perceptions of improvement and satisfaction with their progress were higher (Burgio et al, 1998).

This therapy also has been shown to reduce urgency, frequency, and nocturia in both men and women. As an example, the Male Overactive Bladder in Veterans (MOTIVE) study compared BT with urge suppression to antimuscarinic therapy (extended-release oxybutynin) in men with OAB in the absence of bladder outlet obstruction (Burgio et al, 2011). Mean 24-hour voids decreased significantly in both groups, and these reductions were statistically equivalent.

BT with urgency suppression has also been shown to reduce nocturia in both men and women (Johnson et al, 2005; Burgio et al, 2011; Johnson et al, 2013). Patients are instructed to use urge suppression techniques when they wake up at night with bladder fullness or an urge to void. If the fullness/urge subsides, they are encouraged to go back to sleep. If after a minute or two the urge to void has not subsided, they are advised to get up and void, so as not to interfere unnecessarily with their sleep. Johnson and colleagues (2005) showed that both BT and drug therapy reduced nocturia more than placebo in women, and BT was significantly more effective than drug therapy. In a study in men with nocturia (Johnson et al, 2013), both behavioral treatment (PFMT, delayed voiding and urge suppression techniques) and drug (antimuscarinic) therapy reduced nocturia in men when added to α -blocker therapy, but the addition of behavioral treatment was statistically better than the addition of antimuscarinic therapy for nocturia.

Evidence has shown that combining BT with drug therapy can improve outcomes of drug therapy for urge incontinence. In a multisite trial conducted by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) Urinary Incontinence Treatment Network, women with urge-predominant incontinence were randomized to receive extended-release tolterodine with or without BT. Women who underwent BT in addition to drug therapy reported greater improvements in patient perception of improvement, patient satisfaction, and validated measures of symptom distress and bother while on active therapy, as well as 6 months after drug therapy was discontinued (Burgio et al, 2008).

In addition to being a central element of behavioral training, the urge suppression strategy has been adopted as one of several techniques to help patients postpone voiding in bladder training or delayed voiding programs.

ROLE OF BIOFEEDBACK

BF is not a treatment in itself, but a technique for teaching patients control over physical responses. Commonly known for its role in treatment of headaches, muscle spasm, and hypertension, it is also a very effective method for teaching bladder and PFM control in the treatment of LUTS. **BF helps patients learn by giving them precise, instantaneous feedback of their physiologic responses, such as PFM contraction.** The "perineometer" developed by Dr. Kegel was a BF instrument that assisted women to learn PFM control by giving immediate feedback of efforts to contract PFMs. BF may be especially helpful in patients who are having difficulty identifying and isolating the correct muscles or who need encouragement to continue with prescribed treatment.

Most BF instruments are now computerized and display feedback visually on a monitor (Fig. 80-6). Pelvic floor muscle activity can be measured by manometry or surface electrode electromyography (EMG), using vaginal or anal probes or surface skin electrodes. Signals are enhanced through the computer, and feedback is provided on a monitor for visual feedback or via speakers for auditory feedback (Figs. 80-7 through 80-9). When patients observe the results of their attempts to control PFM activity, learning occurs by means of operant conditioning (trial and error learning).

An advantage of EMG over manometric pressure is that, provided the machinery is of sufficient sophistication with adequate filtering, EMG apparatus can use the newer types of electrodes that

Figure 80-6. Prometheus biofeedback equipment with monitors for visual feedback. (Courtesy Penn Urology, University of Pennsylvania.)

Figure 80-8. Patient viewing biofeedback tracings.

Figure 80-9. Example of a biofeedback graph.

are lightweight and designed to stay in place, hence allowing more functional positions during assessment and treatment. Like other methods, EMG can be multichannel, which allows the simultaneous display of PFM contraction and inhibition of counterproductive accessory muscle contractions (e.g., abdominal, gluteal muscle).

BF-assisted PFMT in conjunction with other conservative treatment components has been tested in several studies, producing mean reductions of UI ranging from 60% to 85% (Moore et al, 2013). BF technology is an excellent method to help patients identify and exercise PFMs, but it is not the only effective method, and it is not considered essential. The literature is inconsistent on the issue of whether BF enhances outcomes of PFMT. A 2011 Cochrane review (Herderschee et al, 2011, 2013) included 24 trials involving 1583 women and concluded that women who received PFMT with BF were significantly more likely to report cure or improvement compared to those who received PFMT alone. However, these studies should be interpreted cautiously because the treatment groups differed on parameters other than BF, such as preparation of the clinician providing the therapy, and women in the BF groups usually had more extensive contact with providers.

PELVIC FLOOR MUSCLE ELECTRICAL STIMULATION

Pelvic floor muscle electrical stimulation with a nonimplanted device involves the application of a low-grade of electrical stimulation to the PFM to stimulate contraction in patients with different types of UI or symptoms of urgency, frequency, and nocturia (Newman and Wein, 2009). Electrical stimulation has a twofold action: contraction of PFMs and inhibition of unwanted detrusor contractions (Schreiner et al, 2013). Electrical stimulation is provided by office-based machines or portable battery-powered stimulators that are used in the office or by the patient at home. These units have different combinations of current types, waveforms, frequencies, intensities, electrode types, and placements.

Pelvic floor muscle electrical stimulation is usually a component of conservative treatment in urologic practice, because clinicians use it to assist in PFM identification (Starr et al, 2013). Patients with LUTS secondary to neurologic disease (e.g., multiple sclerosis) also may benefit from this therapy. Many clinicians institute this treatment in patients who have failed other behavioral treatments and

prescribe home units for long-term treatment. There are two main types of electrical stimulation, as follows:

Long-term or chronic electrical stimulation delivered below the sensory threshold aiming at detrusor inhibition by afferent pudendal nerve stimulation. According to Fall and Lindstrom (1994), the electrically evoked activity results in reflex activation of hypogastric efferents and central inhibition of pelvic efferent mechanisms sensitive to low-frequency stimulation. The device is used for 6 to 12 hours per day for several months.

Maximal electrical stimulation, using a high-intensity stimulus (just below the pain threshold), aims to improve urethral closure by direct and reflexogenic contraction of striated periurethral musculature (Fall and Lindstrom, 1991). Detrusor inhibition by afferent pudendal nerve stimulation also has been suggested as a mechanism (Berghmans et al, 2002). This type of electrical stimulation is applied for short durations (15 to 30 minutes) several times per week (or one to two times daily using portable devices at home).

In the context of conservative therapy, electrical stimulation can be applied using surface skin electrodes, delivering transcutaneous electrical stimulation via suprapubic, sacral, or external anal surface skin electrodes or intravaginal or intrarectal sensors. Parameters for electrical stimulation include current source, pulse width and duration, current intensity (range), stimulus frequency, pulse shape, length of session, total number of sessions, and rest to work ratio, which are varied according to type of UI and type of electrical stimulation. Berghmans and colleagues (2002) reported that frequencies of 5 to 20 Hz are usually used for urgency UI, 20 to 50 Hz for stress UI (including after prostatectomy), and approximately 20 Hz or high and low frequency alternately for mixed UI. Pulse durations range from 200 to 1000 µsec. The pulse shape is generally rectangular, and biphasic pulses are preferred.

The literature on electrical stimulation in women indicates that it is effective for improving stress, urgency and mixed UI compared to sham or no treatment (Moore et al, 2013). However, it does not appear to enhance outcomes over those obtained through PFMT alone or PFMT with BF. Less work has been done examining electrical stimulation in men (Berghmans et al, 2013). Overall, there is little evidence to suggest that electrical

stimulation improves outcomes of PFMT, with or without BF, but it may hasten the recovery of continence after prostatectomy.

BLADDER TRAINING AND SCHEDULED VOIDING REGIMENS

Scheduled voiding regimens, also known as toileting programs, have for decades been a mainstay of treatment for urge UI and OAB. Scheduled voiding regimens include bladder training, timed voiding, habit training, and prompted voiding (Table 80-4). Although these regimens share the common feature of being based on a toileting schedule, they differ on the role of the patient (active vs. passive), how adjustments are made to the voiding schedule, the nature of patient education, the use of reinforcement techniques, and the nature of the patient-provider interaction (Moore et al,

2013). Bladder training is self-administered and requires the patient to resist urgency and delay voiding. Timed voiding, habit training, and prompted voiding most often rely on caregiver involvement.

Bladder Training

Bladder training is a behavioral intervention developed originally for the treatment of urgency UI. Many patients who experience urgency UI or urgency without leakage, tend to void frequently. This response provides immediate relief from the sensation of urgency, but it sets the stage for more and more frequent urination. Once frequent voiding becomes a habit, it can be difficult to change and may lead to reduced functional bladder capacity, detrusor overactivity, and, in some cases, urge UI. Detrusor overactivity produces urgency, completing a cycle of urgency and frequency that is then

TABLE 80-4 Understanding Toileting Programs

TYPE	DEFINITION	KEY COMPONENTS
Timed voiding (or scheduled toileting)	Fixed, predetermined time intervals between toileting	The following is an example of a toileting program that can be used by institutions or caregivers that includes 8 times in a 24-hr period, or every 3 hr: <ul style="list-style-type: none"> • <i>Day:</i> On awakening, after breakfast, midmorning, before lunch, and after an afternoon nap (midafternoon). • <i>Evening:</i> Before dinner and at bedtime. • <i>Night:</i> Determine if person wants to be awakened at night to void and identify times.
Habit training	Fixed voiding schedule based on identified patterns of incontinence to preempt incontinence.	Using a bladder diary, incontinence and voiding patterns are identified and an individualized toileting schedule is developed. In institutions such as nursing homes, a typical toileting schedule may be determined around daily events.
Prompted voiding	Involves prompting and assisting patients to toilet and positive reinforcement for requesting toileting assistance either spontaneously or following verbal prompts from a caregiver.	The major elements of prompted voiding are: <ul style="list-style-type: none"> • <i>Monitoring:</i> The caregiver checks on a regular basis (use toileting schedule described in scheduled toileting) and person is asked to report verbally if wet or dry. • <i>Prompting:</i> The person is asked if they need to void and assisted with voiding. • <i>Praise and encouragement:</i> The caregiver provides if the person is continent. Most successful in individuals who can ask for assistance or void when prompted.
Functional incidental training (FIT)	Combines prompted voiding with functionally oriented, low-intensity endurance and strength-training exercises.	Combine mobility and transfer training with prompted voiding,
Bladder training	Training involves establishing a voiding schedule and incrementally increasing the voiding interval.	Promotes restoration of normal bladder function through incremental voiding schedules and education regarding urge inhibition techniques. Requires person to be able and willing to participate actively. <p><i>Four primary components:</i></p> <ol style="list-style-type: none"> 1. Education program that usually combines written, visual, and verbal instruction addressing the physiology and pathophysiology of the lower urinary tract. 2. Scheduled voiding with systematic delay of voiding that requires the ability to resist or inhibit the sensation of urgency, to postpone voiding, and to urinate according to a timetable rather than according to the urinary urge. 3. Use of techniques to suppress urgency (quick pelvic floor muscle contractions, deep breathing with relaxation, distraction techniques). 4. Gradual increases in voiding interval. 5. Reinforcement through consistent encouragement and positive feedback.

Modified from Flanagan L, Roe B, Jack B, et al. Systematic review of care intervention studies for the management of incontinence and promotion of continence in older people in care homes with urinary incontinence as the primary focus (1966-2010). *Geriatr Gerontol Int* 2012;12:600-11; Newman DK, Burgio KL, Markland AD, et al. Urinary incontinence: nonsurgical treatments. In: Griebing TL. *Geriatric urology*. London: Springer-Verlag; 2014. p. 142; and Newman DK, Wein AJ. *Managing and treating urinary incontinence*. 2nd ed. Baltimore: Health Professions Press; 2009. p. 245-63.

perpetuated. This cycle can be broken using bladder training or a program of progressive delayed voiding.

The goal of bladder training is to restore normal bladder function and capacity using consistent, incremental voiding schedules. First known as bladder drill, it was an intensive intervention that was often conducted in an inpatient setting. Now the program is implemented more gradually in an outpatient setting. Bladder training is a multicomponent intervention that involves patient education regarding LUT function, setting incremental voiding schedules, and teaching urge control techniques to help patients postpone voiding and adhere to the schedule (Fantl et al, 1991; Wyman and Fantl, 1991; Wallace et al, 2009).

Usually bladder training begins with the patient completing a bladder diary to document voiding patterns and frequency. Based on the diary, an initial voiding interval is established (Moore et al 2013). Often, this is a 1-hour interval during waking hours, although a shorter interval (e.g., ≤ 30 minutes) may be necessary at first. Another method is for the clinician to select a voiding interval based on the longest time interval between voids that is comfortable for the patient. The patient is to void on waking in the morning, every time the interval has passed, and just before bedtime. The schedule is increased by 15 to 30 min/week, depending on the patient's tolerance to the schedule (i.e., fewer incontinent episodes than the previous week, minimal interruptions to the schedule, and the individual's control over urgency).

In bladder training, the patient is asked to postpone urination, which for most patients involves coping with the sensation of urgency while they wait. The approach to urgency management used in clinical practice has been to suggest various techniques for relaxation or distraction to another activity (Fantl et al, 1991; Wyman and Fantl, 1991; Wyman, 2007). Patients are encouraged to get their mind off the bladder by engaging in an activity that requires mental but not physical effort (see Fig. 80-5). Common activities include making a telephone call, reading, or making a to-do list. Distracting attention from the bladder in this way can reduce anxiety and allows time for the urge to subside. Also used are affirming self-statements such as "I am in control of my bladder," or "I can wait." Repeated rapid contraction of the PFM (termed "quick flicks") with the individual remaining posturally still and waiting for the sensation to pass has proved to be a useful adjunct to the bladder training regimen for OAB (Newman and Wein, 2009; Payne, 2012; Moore et al, 2013).

Ideally, the provider should monitor a patient's progress on a weekly basis during the training period, make individualized adjustments to the voiding interval, and provide positive reinforcement during the training period. Patient self-monitoring using voiding diaries is a useful tool to help patient and clinician evaluate adherence to the schedule, evaluate progress, and determine whether the voiding schedule should be changed.

The underlying mechanisms of how bladder training works are unknown. However, one of the most important features of bladder training is that it dissociates voiding from urgency, and it may be that voiding by the clock, rather than in response to urgency, weakens the urge-void response. Other hypotheses include improved cortical control of bladder activity and urethral closure, improved central modulation of afferent stimuli, altered behavior because of better awareness of LUT function, and increased bladder capacity.

Evidence for Bladder Training

Several systematic reviews have been published that provide synthesis and grading of evidence for bladder training in the treatment of UI or urgency UI (Berghmans et al, 2000; Roe et al, 2007; Wallace et al, 2009; Moore et al, 2013). The ICI included RCTs with participants who had UI (urge, stress, and mixed), as well as participants who had OAB without UI. Based on 17 trials involving 2462 women and five trials with 142 men, the ICI noted and described remarkable variability in bladder training protocols and concluded that there was no evidence to suggest the most effective method or specific parameters of bladder training. However, they recommend that clinicians provide the most intensive bladder

training supervision that is possible within service constraints (Moore et al, 2013).

From the few trials available of bladder training in women with urge, stress, and mixed UI, the ICI concluded that bladder training is more effective than no treatment, but there was insufficient evidence to draw conclusions on its effect in men. They also found insufficient evidence to draw conclusions on the comparative effectiveness of bladder training and current drug therapy or for their combined effectiveness for women with detrusor overactivity or urgency UI. In a comparative effectiveness review of nonsurgical treatments for UI in women, the Agency for Healthcare Research and Quality (AHRQ) (Shamiliyan et al, 2012) found that UI outcomes did not differ between bladder training and PFMT; nor were there differences between bladder training alone and bladder training combined with PFMT.

Other Scheduled Voiding Regimens

Toileting programs are the cornerstone of continence care for cognitively impaired patients. Other than BT, toileting programs are usually caregiver-dependent, defined as the need for a professional or family caregiver to assist with toileting (Newman and Wein, 2009). Scheduled voiding can be beneficial for toileting-dependent residents in nursing homes or individuals living at home who have an available and willing caregiver. Individuals who have difficulty or require human or mechanical assistance with toileting are referred to as having "toileting disability" (Talley et al, 2014). These individuals may have mobility or cognitive impairment or may need some assistance from at least one person, but are able to cooperate with toileting. The choice of timed voiding, habit training, or prompted voiding program is determined by the cognitive and functional status of the individual, the variability of the voiding pattern, and the need for reinforcement for adherence to the regimen.

Timed Voiding

Timed voiding also has been called scheduled toileting, routine toileting, and fixed toileting. The goal of timed voiding is to prevent incontinence by providing regular opportunities for bladder emptying before the bladder reaches capacity. Keeping the bladder volume below capacity may decrease leakage associated with a detrusor contraction that occurs with a full bladder, as well as decrease leakage that might occur with stress UI. No other physiologic mechanism has been determined. Timed voiding has been recommended for patients who cannot use the toilet independently. It has been used primarily in institutional settings as a passive toileting assistance program, in which a caregiver takes the patient to void every 2 to 4 hours except at night, and for patients with neurogenic bladders associated with multiple sclerosis and other neurologic diseases (Ostaszkiwicz et al, 2004b, 2005b). Ideally, the schedule for toileting is based on some objective measure, such as a bladder diary, on data collected using a bladder volume recording instrument (Newman et al, 2005), or from an electronic device used to monitor and record incontinence episodes (Colling et al, 2003).

Timed voiding is a "passive" type of toileting program, because it takes place regardless of whether patients have a sensation to void, but the schedule is usually followed only during waking hours (Ostaszkiwicz et al, 2005b). The goal is to keep the person dry, and no effort is made to motivate the person to resist the urge to urinate. Although fewer than 20% of frail elders become completely dry with timed voiding, between 30% and 50% of incontinent elders may improve, reducing the number and volume of incontinence episodes. This is probably also true in people being cared for in their homes.

Timed voiding also can be useful for cognitively intact elders who have developed bladder sensory impairment as a result of neurologic conditions. Voiding by the clock, instead of waiting for urgency, and before spontaneous bladder emptying occurs, can prevent or reduce incontinence. A brief, 2- to 3-day trial of timed

voiding can determine if it will be successful for an individual. Timed voiding is also intended to normalize frequency in a patient with infrequent voiding and/or diminished sensation (Payne, 2012).

Habit Training

Habit training is a variant of timed voiding, with the difference being that the toileting schedule is matched to the patient's voiding pattern, rather than being fixed as it is in timed voiding. Using the patient's bladder diary, a toileting schedule is assigned to fit a time interval that is shorter than the patient's normal voiding pattern and to precede the period when incontinent episodes are expected. Thus the voiding interval may be lengthened or shortened throughout the day depending on the patient's voiding pattern, with the goal to preempt incontinence. In the traditional applications of habit training, it is a caregiver-dependent toileting assistance program that is initiated and maintained by the active involvement of a professional or family caregiver (Ostaszewicz, 2004a, 2005a).

Habit retraining has primarily been used in institutional settings with cognitively and physically impaired adults; but it also has been tested with the homebound elderly population (Colling et al, 2003). Habit retraining has applicability for use in unimpaired adults who have a consistent pattern of incontinence that occurs at approximately the same time interval each day or is induced by diuretic use. The interval may be set permanently or gradually increased.

Colling and colleagues (2003) developed a habit training program called Pattern Urge-Response Toileting (PURT) and tested it with 78 caregiver-dependent homebound frail elders. Caregivers in this study were relatives, usually spouses providing care. Three weeks of voiding patterns were obtained from electronic data loggers; individualized toileting schedules were identified based on each person's voiding pattern; and caregivers were taught when and how to provide toilet assistance to the care recipient. The PURT program reduced the number of incontinence episodes over 24 hours by 18%, decreased the mean number of daily episodes from 4.9 to 4.0, and reduced the volume of UI over 24 hours by 39%.

Prompted Voiding

Prompted voiding is a toileting program that combines scheduled voiding with prompting from a caregiver. It is used to teach people with or without cognitive impairment to initiate their own toileting through requests for help and positive reinforcement from caregivers when they do so. It has been used primarily in nursing home settings with cognitively and physically impaired older adults (Schnelle et al, 1989; Burgio et al, 1994; Eustice et al, 2000).

Prompted voiding has three components: (1) regular monitoring with encouragement to report continence status, (2) prompting of resident to toilet on a scheduled basis, and (3) praise with positive feedback when the resident is continent and tries to toilet (Lekan-Rutledge, 2000; Lyons and Specht, 2000). For prompted voiding to be effective, individuals must be able to delay voiding and cooperate with toileting or have awareness of when they need to void.

A systematic review (Flanagan et al, 2012) of four RCTs from 1996 to 2010 of the management of incontinence in care homes using prompted voiding showed a decrease in incontinent episodes. Research on prompted voiding has been conducted mostly in nursing homes and has shown that between 25% and 40% of incontinent residents respond well to toileting assistance; approximately 38% cannot successfully use the toilet when necessary, even when provided help by research assistants (Ouslander et al, 1995). In one study of 191 incontinent residents in seven nursing facilities, 25% to 40% responded well to prompted voiding during the day, with incontinence episodes decreasing from three or four during the day to one or none.

Ouslander and colleagues (2005) combined prompted voiding with other activities of daily living as part of a multicomponent intervention known as Functional Incidental Training (FIT). FIT used a "designated" versus "integrated" nursing assistant role to

combine restorative care including a walking program, exercise therapy, and continence care. This intervention repeatedly has been shown to improve physical function, as well as UI in nursing facility residents (Schnelle et al, 1995; Ouslander et al, 2005). A 3-day trial of prompted voiding can demonstrate whether it is likely to be effective (Ouslander et al, 1995).

Challenges of Caregiver-Administered Voiding Schedules

The impact of a toileting regimen on caregivers can be significant (Roe et al, 2011). UI management has been rated as the third most troublesome caregiving task, behind a lack of time for their own needs and managing the care recipient's emotional and behavioral problems (Colling et al, 2003). Engberg and colleagues (2002) reported areas of caregiver strain in relation to incontinence, including odor (56%), toileting (55%), changing pads and clothing (53%), UI-related costs for pads or briefs (53%), wet clothing (50%), and changing bed linens (44%). Drennan and colleagues (2012) conducted a qualitative study of managing incontinence for people with dementia living at home and found that toilet prompting or reminding can lead to irritation and arguments, because patients perceive this as being treated like a child.

Delayed Voiding

Delayed voiding is another approach to helping patients expand the interval between voids. It differs from bladder training in that patients are not placed on a predetermined voiding schedule. When first experiencing an urge to void, patients are instructed to use their urge suppression techniques until the urge subsides (see Fig. 80-5). However, instead of going to the bathroom immediately after suppressing the urge, they postpone urination by waiting 5 minutes before voiding.

In patients who have experienced urgency UI, even a mild urge to void triggers a trip to the bathroom as soon as possible, because of the fear of leakage otherwise. However, most patients can be convinced to try a 5-minute delay, particularly in safe circumstances such as at home alone. Often, they are surprised to find that after a brief wait, the urge subsides or disappears altogether. This enhances their sense of control and helps restore confidence so that they can gradually increase the delay time to achieve a normal frequency.

BEHAVIORAL TREATMENT FOR VOIDING AND PELVIC FLOOR DYSFUNCTION

PFM dysfunction, especially PFM overactivity, is characterized by elevated resting tone (hypertonicity) and decreased relaxation capacity and manifests in such symptoms as pelvic floor tenderness/pain, pelvic pain, bladder pain syndrome, and/or voiding symptoms, including hesitancy, straining to void, and incomplete bladder emptying. Assessment includes digital palpation of the PFMs to detect tenderness and pain, resting tone, contraction strength, and ability to relax. Some women have an "overactive pelvic floor" characterized by generally high resting tone. Others may have increased muscle tension only when attempting to void.

When muscle tension or spasm is detected, behavioral treatment focuses on teaching conscious relaxation of PFM, especially in the context of voiding. The first step is to educate the patient about bladder and pelvic floor anatomy and function. Normal voiding is a coordinated process in which pelvic floor relaxation precedes and can initiate detrusor contraction and urethral relaxation. Some women habitually void by Valsalva, believing that they need to bear down to push urine out and empty the bladder. This can result in a reflex contraction of the PFMs, impeding urine flow. Patients with dysfunctional voiding need to understand that pushing is not necessary and may be counterproductive. Instead, they can facilitate voiding through voluntary PFM relaxation, which will allow the bladder to empty naturally.

PFMT focuses on developing an awareness of muscle tension as distinct from muscle relaxation. Actively contracting the muscles

demonstrates the sensations associated with muscle tension and assists patients to discriminate and contrast it with the sensations of relaxation. An active contraction also leads to a more complete subsequent relaxation. Perineal or vaginal biofeedback also can be used to bring muscle tension to a conscious level.

Using PFMT to enhance muscle relaxation in patients with high-tone PFM is referred to as *down training*. Teaching a muscle to relax is often more difficult than teaching it how to contract (*up training*). Patients being treated for pain often will benefit from BF-assisted PFMT, which enables them to coordinate PFM movement with the BF visual signal. Once able to feel the muscle release and relax, the patient can begin coordination of muscle relaxation after a contraction.

As with PFM exercises for incontinence, daily exercise involves not only contracting but also relaxing muscles fully between contractions. This is particularly important for patients with voiding dysfunction. To emphasize relaxation, these patients are taught to focus more on the relaxation phase, which is extended with a 1:4 ratio or longer as indicated.

Once the patient has learned the sensation of adequate PFM relaxation during exercise sessions, it is important to address voiding habits, so that the relaxation skills can be generalized. For many women, voiding is an activity that is rushed because of a busy lifestyle and they do not take the time needed to allow normal voiding. **With behavioral treatment, patients are encouraged to create a relaxing environment and plan adequate time for voiding.** They are instructed in good voiding technique. Specifically they are to slow down, take a deep breath, relax their body, relax their PFMs, and wait for the urine to flow. Anecdotally, some women benefit from double voiding or lingering until another detrusor contraction occurs, leading to more complete emptying. A second void can be facilitated by rising up from the toilet seat slightly, sitting back down, and relaxing the PFMs once more.

LIFESTYLE MODIFICATIONS

In addition to the behavioral interventions that improve symptoms through teaching new skills or strategies, there are a number of lifestyle modifications that change a person's habits and/or lifestyle choices to mitigate factors that may contribute to LUTS. Lifestyle modification involves a conscious choice by the individual to change a practice that is under their control and may contribute to LUTS. Lifestyle modifications are sometimes referred to as *self-care practices*. They can be used as a primary intervention in some cases, but usually they are adjunctive. Lifestyle changes include **fluid management, reduction of caffeine and other dietary irritants, addressing constipation, and weight loss.** Although there is much less evidence for lifestyle modifications, these changes can have a significant impact on overall bladder health and have become integral to conservative management (Burgio et al, 2013).

Fluid Management

Fluid intake plays a role in the prevention of several urinary system diseases, and adverse effects on the urinary system can result from insufficient hydration. Modifying the type or volume of fluids, either as a primary or an adjunctive strategy, is often recommended to optimize outcomes as part of conservative intervention for LUTS. Fluid intake modifications depend on the patients' pattern of intake, which can be assessed by having them complete a 24- to 48-hour diary of intake and output, including voided volumes when possible. Reviewing such a diary can reveal excessive fluid intake, inadequate fluid intake, and diurnal patterns of intake that may be contributing to LUTS.

Excessive Fluid Intake

Excessive fluid intake can be a problem when large volume intake triggers symptoms of urgency, frequency, or incontinence (Segal et al, 2011). Fluid intake averaging greater than 3700 mL/day has

been associated with higher voiding frequency and incidence of UI compared with an intake of approximately 2400 mL/day (Miller et al, 2011). In a study of healthy young men, those with excessive fluid intake not only had significantly increased urine volume and frequency but also had significantly elevated bladder pressure on ambulatory urodynamics (Schmidt et al, 2004). Some people increase their fluid intake deliberately in an effort to "flush" their kidneys or lose weight. In others it is simply a habit. In in-depth interviews conducted with participants in the Boston Area Community Health (BACH) study (Elstad et al, 2011), women reporting the need to increase fluid intake attributed it to popular health messages recommending daily fluid intake and that water was "good for you." Men, on the other hand, tended to describe the function of water in the body as to ward off infection, "flush out the kidneys," or "keep your system cool." **When patients consume an abnormally high volume of fluid (e.g., > 2100 mL of output per 24 hours), reducing excess fluids is often an appropriate measure and can be helpful for reducing urgency, frequency, and urge incontinence.**

Inadequate Fluid Intake

In practice, it is more common to see inadequate fluid intake, because people with bladder problems often restrict their intake in an effort to control symptoms. In the BACH study interviews (Elstad et al, 2011), men and women across all three racial/ethnic groups reported decreasing fluid intake to manage or cope with urinary symptoms. Studies of community-residing elders with LUTS also report self-care practices including self-imposed restrictions of fluids to prevent urinary urgency, frequency, and incontinence (Brink et al, 1987; Wyman and Fantl, 1991; Johnson et al, 2000; Miller et al, 2003; Diokno et al, 2004a, 2006; Wyman et al, 2009). Working women also report limiting fluid intake as strategies to avoid urinary symptoms (Nygaard and Linder, 1997; Fitzgerald et al, 2000, 2002).

In some cases, particularly in older adult women, the resulting fluid intake may be inadequate and places them at risk for dehydration. Underhydration may play a role in the development of urinary tract infections (UTIs) and constipation and decrease the functional capacity of the bladder. In a study of 791 female teachers, those who drank less than the volume they desired had more than twice the risk for UTI (Nygaard et al, 1997).

Although it may seem counterintuitive, it is usually good advice to encourage patients to consume at least six 8-oz glasses of fluid each day to maintain adequate hydration. **Fluid intake should be regulated to six 8-oz glasses or 30 mL/kg body weight per day with a 1500 mL/day minimum at designated times unless contraindicated by a medical condition.** The Institute of Medicine issued a report in 2004 with guidelines for total water intake for healthy people (Institute of Medicine and Food and Nutrition Board, 2004). That recommendation for women was 2.7 L/day, but was intended to include water consumed through both beverages and food. This food versus fluid component has been a source of confusion for the public and professionals alike, with a misperception of fluid source as only deriving from beverage intake.

A useful strategy to encourage increased fluid intake when appropriate is to point out that concentrated urine has a stronger odor than more dilute urine. Patients with incontinence are often quite sensitive about urinary odor and welcome a suggestion to decrease odor.

Timing of Fluid Intake

Although overall fluid restriction is not a good strategy, it can be very helpful to restrict fluids at particular times when toilet access will be limited, such as before a social outing. Patients using temporary fluid restriction should be encouraged to keep their total daily fluid intake optimized, by making up the missed fluids earlier or later.

Avoiding excessive fluid intake in the evening hours can also be helpful for reducing nocturia (e.g., 3 to 4 hours before bedtime).

In patients who retain fluid during the day and have nocturia because of mobilization of fluid during sleep, behavioral interventions focus on managing daytime accumulation of fluid. Patients are advised to wear support stockings to prevent accumulation of edema fluids or to elevate the lower extremities in the late afternoon to mobilize the fluid well before bedtime.

In some patients, a midafternoon to late afternoon loop diuretic is useful to complete diuresis before bedtime. For patients who are already taking a loop diuretic, nocturia often can be improved by altering the timing of the diuretic (so that most of the effect has occurred before bedtime). Loop diuretics are also known to aggravate incontinence by increasing the rate of bladder filling and producing sudden urges. Such effects sometimes can be avoided by discontinuing the diuretic, changing to a nonloop diuretic, or altering the timing of administration. An example is taking the loop diuretic *after* coming home from work so that diuresis can be accomplished during the evening, but before bedtime.

Evidence for Fluid Management

Although fluid management is widely used in clinical practice there is little scientific evidence on fluid intake related to bladder health. Two small randomized trials suggest a negative effect for increased fluid intake. In one study ($n = 24$), adults with OAB were randomized to either decrease or increase of fluids (Hashim and Abrams, 2008). When patients decreased their fluid input by 25%, there was a significant reduction in daytime frequency (23%), urgency (34%), and nocturia (7%). Increasing fluid input by 25% and 50% resulted in a worsening of daytime frequency but had no effect on urgency, nocturia, or urge incontinence. In a study of women with urodynamically confirmed idiopathic detrusor overactivity ($n = 30$), decreasing fluid intake significantly decreased voiding frequency and urgency incontinent episodes (Swithinbank et al, 2005). However, the Nurses' Health Study, which prospectively investigated the association between total fluid intake and incident UI over 4 years in 65,167 women, found no association between fluid intake and UI (including stress, urgency, and mixed UI) (Townsend et al, 2011).

Caffeine Reduction

Caffeine plays a role in symptoms of urgency, frequency, and urge incontinence partly because it is a diuretic and partly because it is a bladder irritant for many people. The consumption of caffeinated beverages, foods, and medications is easily underestimated. Caffeine is found in many foods and drinks that people consume daily, particularly coffee and tea. Caffeine is consumed regularly by more than 85% of adults in the United States (Mitchell et al, 2014). Approximately 73% of children consume caffeine on a given day and coffee and energy drinks represent a greater proportion of caffeine intake than soda intake, which has declined (Branum et al, 2014).

Urodynamic studies have shown that caffeine increases detrusor pressure (Creighton and Stanton, 1990) and is a risk factor for detrusor overactivity (Arya et al, 2000; Holroyd-Leduc and Strauss, 2004). Caffeine promotes LUTS via decreased threshold of sensation at filling phase and increased flow rate and voided volume (Jura et al, 2011; Lohsiriwat, et al, 2011). Lohsiriwat and colleagues (2011) found that caffeine, at a dose of 4.5 mg/kg, caused diuresis and decreased threshold of bladder sensation at filling phase, with an increase in flow rate and voided volume. Similarly, daily administration of oral caffeine (150 mg/kg) resulted in detrusor overactivity and increased bladder sensory signaling in the mouse (Kershen et al, 2012).

Caffeine intake also has been associated with LUTS in epidemiologic studies, in both men (Davis et al, 2013) and women (Jura et al, 2011; Townsend et al, 2012; Gleason et al, 2013). Data from the Nurses' Health Study II reported that 25% of these participants experienced frequent (at least once a week) UI with high caffeine intake (Townsend et al, 2012). The BACH study reported on beverage intake and LUTS in a large cohort ($n = 4144$) (Maserejian et al, 2013). Women who had increased coffee intake by at least two

servings per day had 64% higher odds of progression of urgency. Women who had recently increased soda intake, particularly caffeinated diet soda, had higher symptom scores, urgency, and LUTS progression.

In men, greater coffee intake (>2 cups/day vs. none) or total caffeine intake at baseline increased the odds of storage symptom progression (Maserejian et al, 2013). Davis and colleagues (2013) also found that caffeine consumption (equivalent to ~ 2 cups of coffee daily; 250 mg) was significantly associated with moderate-to-severe UI in men in the United States.

There is also evidence that reducing caffeine intake can help reduce episodes of both stress and urgency incontinence (Tomlinson et al, 1999; Gray, 2001; Bryant et al, 2002). Based on the literature, the ICI recommends decreasing caffeine intake to improve continence (Moore et al, 2013). However, the amount of caffeine reduction necessary to prevent associated LUTS is not known.

Many patients are reluctant initially to forgo their caffeinated beverages, but they may be convinced to try it for a short period, such as 3 to 5 days, to determine if they are sensitive to its effects. If they experience relief from their symptoms, they are often more willing to reduce or eliminate caffeine from their diet. To avoid symptoms of caffeine withdrawal, most notably headaches and irritability, it is recommended that caffeine reduction be approached gradually and include mixing caffeinated and decaffeinated beverages incrementally over several weeks.

Other Dietary Irritants

Although data are scarce, a number of other substances are thought to irritate the bladder, including sugar substitutes (aspartame), citrus fruits, highly spiced foods, and tomato products. There are innumerable clinical cases in which these substances appear to be aggravating urgency and incontinence, and reducing them has provided clinical improvement. However, this should not be interpreted to mean that all patients with LUTS should eliminate these foods from their diets. A diary of food and beverage intake is useful for identifying which substances are in fact irritants for individual patients; and a trial period of eliminating these substances one at a time can be used to confirm the relationship.

It also has been suggested that alcohol intake can contribute to urgency, frequency, and incontinence by means of a diuretic effect. However, there is little in the literature to support this hypothesis. In a study of alcohol consumption and UI among community-dwelling Japanese women (Hirayama and Lee, 2012), increases in risk of UI with alcohol drinking and mean ethanol intake did not reach statistical significance. Research is needed in the effect of caffeinated alcoholic beverage and LUTS because consumption is widespread among young adults in the United States (MacKillop et al, 2012).

Bowel Function

Bowel disorders, including chronic constipation (fewer than three stools per week) and straining during defecation, have been linked to LUTS (Cardozo and Robinson, 2002; Carter et al, 2012), and the ICI committee concluded there is "some evidence" to suggest that chronic straining may be a risk factor for the development of UI. The close proximity of the bladder and urethra to the rectum and their similar nerve innervations make it likely that there are reciprocal effects between them. As early as 1988, Lubowski and associates reported that denervation of the external anal sphincter and PFMs may occur in association with a history of excessive straining on defecation (Lubowski et al, 1988). Many believe that if straining is a lifetime habit, it may have a cumulative effect on pelvic floor and bladder function as well. Further, animal studies and clinical data support bladder-bowel cross-sensitization, or crosstalk between the bowel and bladder (Kaplan et al, 2013).

The Epidemiology of Lower Urinary Tract Symptoms (EpiLUTS) II (Coyne et al, 2011) survey ($n = 2160$) indicated that OAB is more

likely to be reported by both men and women with chronic constipation. In a case-control study of women with LUTS ($n = 820$) and matched controls ($n = 148$), constipation and straining during defecation were significantly more common among the women with LUTS, including detrusor overactivity and urgency, than among the controls (Manning et al, 2003).

Fecal impaction and constipation have been cited as factors contributing to urinary incontinence in women, particularly in nursing home populations (Ouslander and Schnelle, 1995). Fecal impaction can be an irritating factor in OAB or obstruct normal voiding, causing incomplete bladder emptying and overflow incontinence. Disimpaction provides immediate relief for some patients, but a bowel management program is usually needed to avoid recurrence.

Self-care practices that promote bowel regularity are an integral part of any behavioral treatment plan. Initial assessment should include questions about bowel history and bowel habits. When constipation is reported, recommendations include ensuring adequate dietary fiber and fluids to ensure normal stool consistency. Sufficient fluid intake is necessary for fiber supplementation to be effective. Also helpful are regular exercise, external stimulation, and establishment of a regular time for bowel evacuation, preferably after a meal to capitalize on postprandial bowel motility.

Obesity and Weight Reduction

Obesity is an established risk factor for UI. A large amount of epidemiologic data, including several systematic reviews, demonstrates an association between body mass index (BMI) and UI, as well as other LUTS, including urgency and frequency (Dallosso et al, 2003; Subak et al, 2009a; Vaughan et al, 2012; Milsom et al, 2013; Khullar et al, 2014). Further, reductions in UI have been observed in morbidly obese women who have had dramatic weight loss after bariatric surgery (Bump et al, 1992; Burgio et al, 2007; Knoepf et al, 2013) and in women who achieved moderate weight loss through supervised behavioral weight-loss programs (Bump et al, 1992; Subak et al, 2005, 2009b; Wing et al, 2010a).

Knoepf and colleagues (2013) reported on the resolution and incidence of UI in women undergoing bariatric surgery, by examining national claims data for 3765 cases with 3 years of follow-up claims data. After surgery, 62.4% of patients (83 in 133) diagnosed with UI before their surgery no longer had a coding diagnosis of UI. In contrast, only 42.1% (56 in 133) of those in a nonbariatric surgery cohort lost their coding diagnosis of UI ($P = .0009$). Incidence of new UI did not differ significantly between the groups, however.

Even moderate weight loss has been shown to improve bladder symptoms in overweight women. In fact, loss of 5% to 10% of body weight, sustained over a 12-month period, can decrease incontinence episodes as much as 70% (Bump et al, 1992; Subak et al, 2005; Wing et al, 2010b). The most definitive of the studies is an RCT comparing the effects of an intensive 6-month, group-administered, weight loss program (including diet, exercise, and behavior modification) to a structured education control program (Subak et al, 2009b). Both groups also received a booklet describing a step-by-step self-administered behavioral program to reduce incontinence. After a mean weight loss of 8.0%, the weight loss group reported a significantly greater reduction in incontinence episodes compared to the control group with a mean weight loss of 1.6% (mean = 47% vs. 28%). Thus weight loss can be a useful component of a behavioral program for incontinence in overweight women.

Based on this evidence, more clinicians should recommend weight loss as a component of lifestyle interventions for UI in overweight women (Vissers et al, 2014). Given that BMI is a modifiable risk factor, it is plausible that UI may be prevented if women maintain their weight within suggested guidelines.

ADHERENCE TO CONSERVATIVE TREATMENT

It is widely accepted that the effectiveness of conservative treatments relies on the active participation of an involved and motivated

patient. In fact, most behavioral interventions can be conceptualized as self-management. Therefore the greatest challenge for the clinician becomes how to motivate patients to be actively involved in their care, follow their daily program consistently, and persist for long enough to experience meaningful change in their symptoms. Progress in behavioral programs is typically gradual, which makes compliance even more difficult for patients who expect immediate results. Clinicians can optimize patient adherence by making it clear that it may take weeks to months for symptom improvement, and it may be irregular, with “good” days and “bad” days. Clinicians can provide support by scheduling follow-up appointments to maintain accountability, track and reinforce progress, identify and address barriers, adjust the daily regimen, encourage persistence, and let the patient know that she is not alone.

Measurement of adherence to behavioral protocols often has been overlooked in research (Dumoulin et al, 2015). Few studies provide information about how adherent patients were with PFM exercise, behavioral strategies, voiding schedules, or other components of behavioral treatment (Bø et al, 1996, 1999; Mørkved et al, 2002; Fine et al, 2007; Borello-France et al, 2010); and the literature is sparse on methods to identify barriers and improve adherence (Alewijns et al, 2003; Borello-France et al, 2010, 2013; Hay-Smith et al, 2015).

Borello-France and colleagues (2013) reported on adherence to PFM exercise and bladder control strategies as a secondary analysis of a multisite RCT comparing three interventions for stress-predominant UI, intravaginal continence pessary versus multicomponent behavioral therapy (including PFMT and bladder control strategies), versus pessary and BT combined (Richter et al, 2007). The authors concluded that adherence to PFM exercises and bladder control strategies, when implemented by trained interventionists, can be high and sustained over time. The most common barriers to adherence were trouble remembering to exercise and difficulty finding time. To help patients overcome these barriers, clinicians can use various forms of reminders (e.g., timers), link daily exercises to environmental cues, and integrate exercises into the patient’s everyday activities.

Although most clinicians agree that adherence to maintenance protocol is necessary for long-term effectiveness, there is little work on the durability of behavioral treatments. Long-term studies have shown that women following a PFMT program tend to decrease their adherence over time (Fine et al, 2007). Bø and Hilde (2013) reported that long-term adherence to PFMT varied between 10% and 70%. The few studies of long-term outcomes are inconsistent, but promising, in that many patients are able to sustain improvements in bladder control over time (Cammu and Van Nylén, 1995; Bø and Talseth, 1996; Weinberger et al, 1999). There is clearly a need for more studies of long-term outcomes to understand the reasons for regression and learn how the effects of treatment can be maintained over a lifetime.

ROLE OF CONSERVATIVE INTERVENTIONS FOR PREVENTION OF URINARY INCONTINENCE

Primary prevention of UI using behavioral interventions, including PFMT, behavioral training, or lifestyle changes (i.e., weight loss, fluid moderation, diet modification) have been investigated in four at-risk populations: older women, childbearing women, obese women with diabetes, and men undergoing prostatectomy (Shamilyan et al, 2007; Sievert et al, 2012; Moore et al, 2013; Newman et al, 2013).

Older Women

Age is perhaps the most established risk factor for UI in men and women, yet little work has been done to study approaches to preventing UI in this population. The first prevention study was an RCT comparing a group behavior modification program to no intervention in continent, postmenopausal women, 55 years and older, to determine whether the behavioral intervention could prevent UI,

increase pelvic floor muscle strength, and decrease voiding frequency (Diokno et al, 2004b). At 12 months, the treatment group had statistically significantly better outcomes than the control group in continence status, pelvic floor muscle strength (pressure score and displacement score), improved voiding frequency, and interviod interval.

Later, a smaller study was conducted in 43 women, 65 years and older, residing in an independent-living facility to determine the feasibility of a 6-week pelvic fitness and educational program to control UI and OAB (Dugan et al, 2013). Statistically significant improvements in bladder symptoms were found after 6 weeks in the treatment group, based on visual analog scale scores for symptom bothersomeness, symptoms distress (Urogenital Distress Inventory, Short Form), and impact on quality of life (Incontinence Impact Questionnaire, Short Form).

Childbearing Women

Pregnancy and childbirth are established risk factors for UI in women. For this reason, most prenatal classes include teaching about the role of the pelvic floor and PFM exercises. There is also a growing body of evidence for the preventive value of formal PFMT. Research with primiparous women has shown that intensive antenatal PFMT, including one-on-one instruction to ensure proper muscle control and continued supervision of training, can prevent the development of UI during pregnancy (35 to 36 weeks' gestation) and short-term postpartum (6 weeks to 6 months) (Boyle et al, 2012, 2014; Moore et al, 2013; Mørkved and Bø, 2013; Pelaez et al, 2014). Less clear is the impact of PFMT for preventing UI long term and in multiparous women. Based on research to date, the ICI committee (Moore et al, 2013) recommends (1) an intervention comprising a daily home PFMT and weekly health professional-led exercise classes for 12 weeks, starting at 20 to 24 weeks' gestation for pregnant women having their first baby, and (2) an individually taught strengthening PFMT program that incorporates adherence strategies for postpartum women who have had a forceps delivery or a vaginal delivery of a large baby (≥ 4000 g).

Men Undergoing Prostatectomy

Postoperative UI is almost universal immediately after prostatectomy. Although continence status usually improves in the ensuing weeks and months, it is possible to speed the recovery of continence using behavioral interventions such as PFMT. One approach is to teach men how to control their PFM before surgery, so they will have the opportunity to practice using their muscles in advance of needing to use them more actively after surgery. In one trial, a single session of BF-assisted BT reduced the duration of UI, as well as severity of symptoms in the 6 months after radical prostatectomy (Burgio et al, 2006).

Another approach is to initiate PFMT immediately after catheter removal or early in the recovery period. Results of this approach are inconsistent, but generally show benefit for the training at least in the first 3 months. Trials that have combined preoperative and early postoperative training also indicate that severity of post-prostatectomy UI can be reduced with PFMT, in the short-term (3 months) and in some studies up to 12 months (Hirschhorn et al, 2014). According to Moore and colleagues (2013), whether PFMT should be delivered in the form of hands-on therapy or verbal instruction and support remains unclear.

Urology practices have begun to include various levels of PFMT for men undergoing radical prostatectomy (Newman et al, 2014); however, translation from research to practice has not been optimum, because most men undergoing radical prostatectomy do not receive instruction on PFMT. Some clinicians take the approach of watchful waiting and reserve treatment for men with persistent UI. However, even transient UI can be distressing for men recovering from prostatectomy and hastening the return of bladder control may be important to their activity level, social life, or general well-being.

MECHANICAL VAGINAL AND URETHRAL DEVICES FOR INCONTINENCE

Mechanical devices are of two main types: those that are placed in the vagina to support the bladder neck and urethra, and those that are placed in the urethra or at its opening to block the passage of urine. Mechanical devices are most commonly used for stress UI, but they also have been used for urge and mixed incontinence. A 2011 Cochrane review (Lipp et al, 2011) of mechanical devices noted that many have been developed over the past two to three decades, but few are available in the United States. This review noted there was not enough evidence to recommend any specific type of device or to determine whether mechanical devices are better than other forms of treatment. The ideal mechanical device is one that can adequately control urine leakage, is easy to insert, has few adverse effects, and is of low cost. This is a short review of devices currently in use.

Intravaginal Devices

Women who leak urine during physical activities may benefit from a mechanical device that provides pelvic support. When pelvic support tissues are weak, the urethra may drop to a position where increased abdominal pressure cannot be transmitted to the urethra to assist with urethral closure. Intravaginal devices aim to restore the position of the upper urethra to above the level of the pelvic floor where intra-abdominal pressure can improve its closure. This can be accomplished using an incontinence pessary (Figs. 80-10 through 80-12).

Incontinence pessaries are intended to prevent urine loss by stabilizing and supporting the bladder neck or compression of the urethra during increases in intra-abdominal pressure. Some women who have urinary urgency and frequency because of pressure from a pelvic organ prolapse also may benefit from the support of an incontinence pessary.

Pessaries are made of an inert plastic or silicone material to prevent odors and absorption of vaginal secretions. There are very few contraindications to pessary use, but a pessary should not be placed in patients with evidence of an active pelvic infection, severe ulceration, or allergy to silicone or latex or in patients who are likely to be noncompliant with maintenance care and follow-up appointments. Common side effects include vaginal discharge and odor. Serious complications from pessaries are rare; however, vesicovaginal fistula, rectovaginal fistula, erosion, and subsequent impaction have been reported (Arias et al, 2008; Penrose et al, 2014).

Difficulty with self-removal and insertion may limit more widespread use of currently available pessaries.

Research on pessary use for incontinence is limited. One device that has been studied is the Uresta (EastMed, Halifax, Nova Scotia), a bell-shaped pessary (Fig. 80-13) with a handle at its base for easy insertion and removal. Its narrow tip allows for easy insertion into the vagina, like a tampon, and it positions itself so that the wide base provides support to the urethra. Farrell and colleagues (2007) tested this pessary in 32 women. Leaking episodes decreased by 4 per week (based on 7-day diary) ($P = .028$) and pad weights by 11 g ($P = .006$). No complications were reported. At 2 weeks, 66% of women were satisfied with the pessary. After 12 months, 50% of subjects continued pessary use with statistically significant differences in number of leakage episodes, pad weight, symptom severity, and impact on quality of life.

A multisite randomized trial of a continence pessary compared to behavioral therapy was conducted by the Eunice Kennedy Shriver National Institute of Child Health and Development (NICHD) Pelvic Floor Disorders Network (Richter et al, 2010). The Ambulatory Treatments for Leakage Associated with Stress-Incontinence (ATLAS) trial randomized 446 women with stress-predominant incontinence to intravaginal pessary, BT, or combined treatment. At 3 months, 40% of the pessary group and 49% of the behavioral group rated themselves as “much better” or “very much better,” but these outcomes were not statistically different. Significantly more

Figure 80-13. Uresta pessary. (Courtesy EastMed, Dartmouth, NS, Canada.)

women in the behavioral group than in the pessary group, reported having no bothersome incontinence symptoms (49% vs. 33%) and treatment satisfaction (75% vs. 63%). At 12 months, patient satisfaction remained above 50% for all treatment groups, but group differences were not sustained on any measure.

Sze and Hobbs (2014) performed a comparative retrospective parallel cohort study of women whose OAB was treated with ring pessary or multicomponent BT (BT while using PFM exercises to suppress urinary urgency as needed) over a 42-month period. Ring pessary and BT had similar cure rates (29 in 150 [19%] vs. 46 in 231 [20%], respectively).

There is also evidence that tampons, disposable vaginal guards, and an intravaginal bladder neck prosthesis can alleviate stress UI symptoms (Lipp et al, 2011). It is possible that intravaginal tampons may perform as well as more formal mechanical devices, and they are widely available and familiar to women. They are also without significant adverse effects and are a less expensive option. The most recent device available is Impressa (Kimberly-Clark, Irving, TX). It is a disposable device that anchors in the vagina using support poles to stay in place. This product is available in retail stores.

Urethral Inserts and Meatal Occlusive Devices

Intraurethral devices are also known as urinary control inserts and urethral inserts. These devices act by simply blocking the passage of urine through the urethra. The devices are thought not to be effective in patients with a fibrotic urethra, in which the fibrosis limits the transmission of pressure. Only one of these, the FemSoft Insert (Rochester Medical, Stewartville, MN) is currently in use.

The FemSoft insert is a sterile, disposable, single-use intraurethral device. It consists of a narrow, silicone tube entirely enclosed in a soft, thin, mineral oil-filled silicone sleeve. The silicone sleeve forms a balloon on the tip of the insert. As the FemSoft Insert is advanced into the urethra, fluid in the balloon is transferred toward the external retainer to facilitate passage through the urethra (Fig. 80-14). Once the tip of the insert has entered the bladder, the fluid returns to fill the balloon, forming a mechanical barrier to retain urine within the bladder.

To assist with insertion, the insert is supplied on a disposable applicator and with a lubricating gel. The device is easily removed for normal voiding and should be removed at least once every 6 hours. This product is a single-use, disposable device. It is available in three diameters (16, 18, 20 Fr) with two lengths (3.5, 4.5 cm) for each diameter, and it is important that the insert be properly sized to the woman. The FemSoft insert is a prescription device and costs less than \$2. Contraindications for use include urgency UI (as bladder contraction would expel the insert), active UTI, urethral stricture, and any anatomic or pathologic urethral condition in which passage of a catheter is not clinically advisable (Newman and Wein, 2009). Adverse events include hematuria and UTI (Sirls et al, 2002).

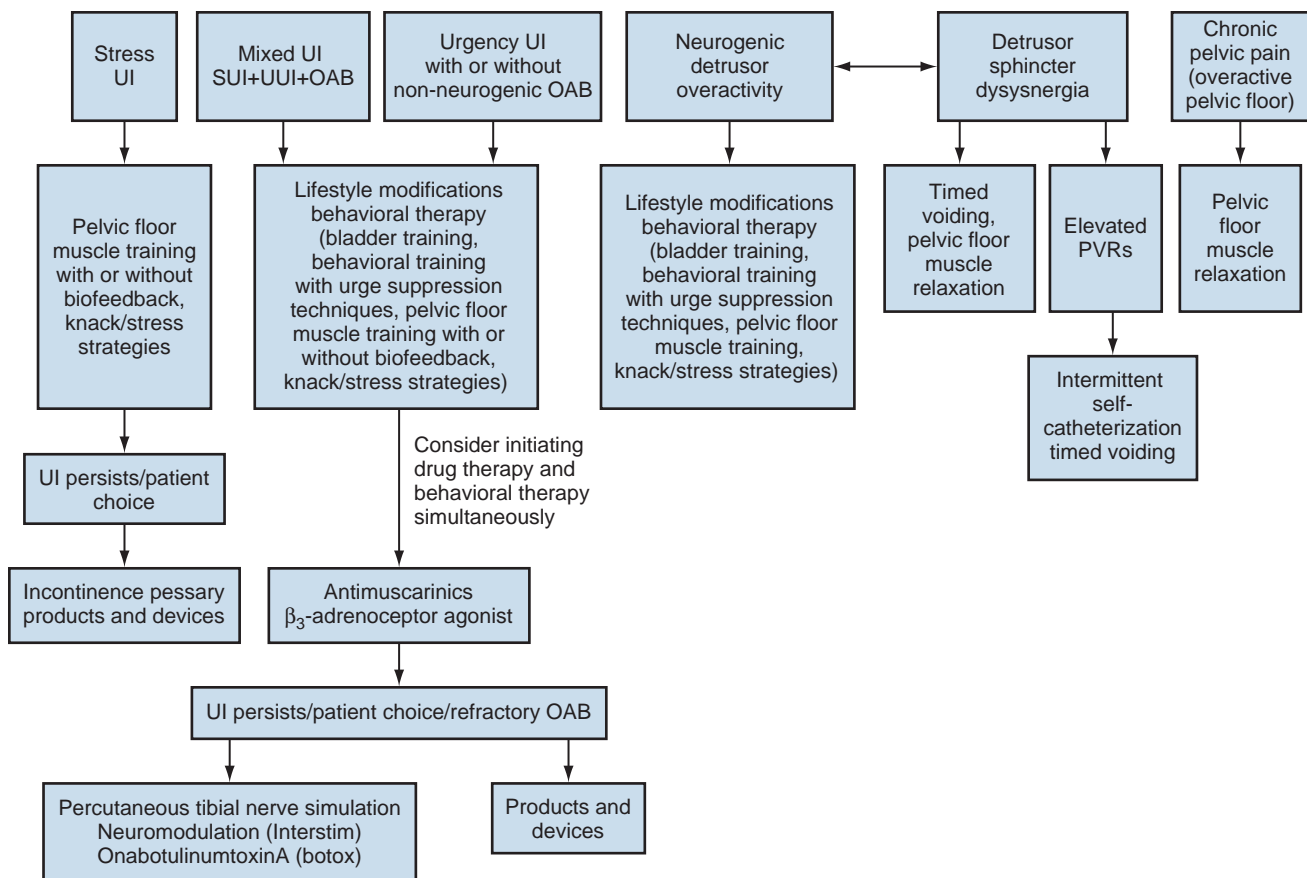

Figure 80-15. Behavioral treatment pathway for the treatment of lower urinary tract symptoms. OAB, overactive bladder; PVRs, postvoid residuals; SUI, stress urinary incontinence; UI, urinary incontinence; UUI, urge urinary incontinence. (Copyright 2013 Diane K. Newman.)

BEHAVIORAL TREATMENT MODEL FOR UROLOGY PRACTICE

Despite the evidence for the effectiveness of behavioral treatments for UI and other LUTS, and guidelines recommending them as first-line therapies, these conservative interventions are not well integrated into clinical practice in many areas. One limitation is the availability of qualified providers. However, **one successful model that has emerged in urologic practice is the integration of advanced practice providers, including continence nurse practitioners and physician assistants.** Historically, advanced practice providers have embraced behavioral treatments as a specialty practice for nonsurgical treatment of a wide range of LUT conditions. An algorithm for a behavioral treatment pathway can be found in [Figure 80-15](#).

Urology lends itself to a multidisciplinary model of a Bladder and Pelvic Floor Disorder service that provides comprehensive surgical and medical care. These centers usually offer the combined knowledge of a multidisciplinary group of experts in the field of UI, voiding, and pelvic floor dysfunction. Changes in reimbursement for nonsurgical treatments such as BF-assisted PFMT, electrical stimulation, and posterior tibial nerve stimulation have allowed urologists, to consider the expansion of current treatments (pharmacologic and surgical) to alternative multifaceted behavioral treatment programs.

KEY POINTS

- Behavioral treatments are a group of interventions that improve LUTS by changing patients' behavior or environment or by teaching new skills.
- There is strong evidence that conservative interventions are effective first-line treatments for patients with LUTS.
- The effectiveness of conservative treatments relies on the active participation of an involved and motivated patient.
- Intensive behavioral interventions that involve an experienced clinician have been shown to be more effective.

History of Electrical Stimulation

Neurophysiology of Electrical Stimulation for Storage and Emptying Disorders

Electrical Stimulation for Storage Disorders

Electrical Stimulation for Emptying Disorders

Future Research and Conclusions

For the past century, the development of electrical neurostimulation and neuromodulation to alter physiologic processes responsible for lower urinary tract symptoms (LUTS) and lower urinary tract dysfunctions (LUTD) largely has been the result of important landmark discoveries in the clinical application of electricity and in the understanding of neuromuscular physiology. In neurostimulation the use of electrical stimuli on nerves and muscles has mainly been developed to achieve immediate clinical responses in neurogenic conditions of pelvic organ dysfunction; in neuromodulation the application of electrical stimuli to nerves has been developed to alter neurotransmission processes in non-neurogenic and neurogenic conditions. In this chapter the focus is on reviewing the application (Table 81-1) and clinical outcomes of neurostimulation and neuromodulation therapies for pelvic organ dysfunction with respect to the development of our knowledge of pelvic neuromuscular physiology and its role in translational innovations.

HISTORY OF ELECTRICAL STIMULATION

Although the field of electrical stimulation of nerves to achieve muscle contractions was not truly realized until the early 1800s, its roots can be traced into the 1700s, when inadvertent electrical impulses were found to generate strong muscle convulsions (Bell, 1811; Clarys, 1994). Magendie (1822) was one of the first to conduct physiologic investigations of the spinal nerve roots, documenting in young dogs that transection of the posterior (dorsal) segments resulted in a lack of sensation but persistence of motor function, whereas anterior (ventral) root transection yielded preservation of sensation yet abolishment of motor function. These important findings created the foundation for our understanding of basic neurophysiology of micturition and led to further discoveries on bladder function in the setting of selective rhizotomy of both the pelvic and hypogastric nerves (Giannuzzi, 1863; Langley and Anderson, 1895). Ultimately, Saxtorph in 1878 used these principles to directly stimulate the bladder in patients with urinary retention via a metal transurethral catheter (Madersbacher, 1999). His early findings allowed others to develop enthusiasm for direct stimulation of the bladder through both transurethral and direct detrusor routes (see section on direct stimulation).

Because Saxtorph had significant influence on the idea that direct bladder stimulation may lead to bladder contractility, McGuire used some of these same principles to perform direct bladder stimulation in dogs (Boyce et al, 1964). He concluded that multiple pairs of electrodes were required to achieve a more uniform pressure rise

within the bladder during the stimulated contraction. Research continued throughout the late 1900s and moved toward development of new electrodes (Susset and Boctor, 1967) and differing wire configurations (Timm and Bradley, 1969; Tscholl et al, 1971).

Direct pelvic nerve stimulation and pelvic floor muscle stimulation were not well-known or well-studied concepts until the mid-1900s because emphasis was clearly on different areas of direct stimulation (i.e., bladder). Dees (1965) studied the bladder contraction state after stimulation to the pelvic nerve. He achieved contraction of both the detrusor muscle and urethral sphincter in a cat model and produced pain and hind leg contraction as well. Others demonstrated similar findings of nonspecific contraction of the bladder and pelvic floor and other areas with direct pelvic nerve stimulation and ultimately realized that direct pelvic nerve stimulation may not be suitable for treatment of bladder dysfunction (Burgele et al, 1962; Hald et al, 1966; Holmquist and Olin, 1968). It appears that direct pelvic nerve stimulation elicits pudendal nerve activity such that outlet resistance is increased, as is pain, through simultaneous hypogastric nerve stimulation. Thus, with the limited-potential clinical utility of the pelvic nerve for stimulation, efforts focused on the pelvic floor muscles, spinal cord, and sacral roots. Caldwell and colleagues first reported experience with pelvic floor muscle stimulation with the goal of improving fecal continence and later urinary incontinence (Caldwell, 1963; Caldwell et al, 1965). Subsequently, interest increased and efforts toward external stimulation were described by anal, vaginal pessary, and direct vaginal stimulation (Hopkinson and Lightwood, 1967; Alexander and Rowan, 1968; Erlandson et al, 1977; Fall et al, 1977).

Spinal cord stimulation, by attempting to directly activate the micturition center, was thought to be a promising avenue of therapy (Nashold et al, 1971; Jonas et al, 1975; Jonas and Tanagho, 1975). Still, as in pelvic nerve stimulation, voiding was initiated; however, simultaneous sphincter activity precluded proper emptying. The subsequent series of developments pursued therapy for incomplete emptying by affecting not only bladder stimulation but, in some way, sphincter relaxation as well.

In 1972, Brindley (1972, 1974, 1977) began experimentation of sacral root stimulation that led to implantation of sacral anterior root stimulators in paraplegic patients with urinary incontinence. Evolving data showed that, for optimal bladder emptying to be achieved, sacral anterior root stimulation with posterior rhizotomies of S2, S3, and S4 would be required (Sauerwein, 1990). The posterior rhizotomy would decrease the reflex activity of the detrusor and improve bladder compliance. Tanagho and Schmidt (1982) then began further examining the sacral roots and their individual contributions to bladder and outlet function. In 1982,

TABLE 81-1 Potential Applications of Electrical Stimulation in the Treatment of Voiding Dysfunction

PURPOSE	SITES OF STIMULATION	MECHANISM
FACILITATE FILLING-STORAGE		
Inhibit detrusor contractility	V, A, SP, PT CP, SR, IV	Neuromodulation
Increase bladder capacity		
Decrease urgency and frequency		
Decrease nociception	V, A, SP, SR	Neuromodulation
Increase outlet resistance	V, A, SR	Direct stimulation (efferent nerves or roots)
FACILITATE EMPTYING		
Stimulate detrusor contraction (spinal cord–injured patient)	SAR	Direct stimulation (efferent nerves or roots)
Restore micturition reflex (idiopathic retention)	SR, IV	Neuromodulation

A, anal; CP, common peroneal; IV, intravesical; PT, posterior tibial; SAR, sacral anterior (ventral) roots; SP, suprapubic; SR, sacral roots; V, vaginal.

TABLE 81-2 Sacral Nerve Responses

SACRAL NERVE	MOTOR AND SENSORY RESPONSE
S2	<i>Motor:</i> Plantarflexion of the entire foot with lateral rotation and clamp movement of the anal sphincter <i>Sensory:</i> Sensations in the leg and buttock
S3	<i>Motor:</i> Dorsiflexion of the great toe and bellows reflex (anal wink) <i>Sensory:</i> Paresthesias or sensation of pulling in the rectum, scrotum, or vagina
S4	<i>Motor:</i> Bellows reflex only <i>Sensory:</i> Sensation of pulling in the rectum only

Tanagho and Schmidt presented initial experience in sacral root stimulation in paraplegic dogs. In this initial study they realized the design of a spiral electrode to minimize nerve damage and fixed the lead wire to the sacral lamina, thereby preventing tension on the electrode itself. They ultimately attained good bladder contraction in these dogs, with minimal sphincteric response. From these initial good results, Tanagho and coworkers then began human trials and characterized the sacral root stimulation patterns and the corresponding muscle responses (Table 81-2). In the course of the neurostimulation developments these researchers realized that sphincteric contraction abolished detrusor activity, and the role of the pudendal nerve and its modulation of bladder capacity began to evolve (Tanagho and Schmidt, 1988; Schmidt, 1989). Thus neuromodulation was introduced as a concept by which activation of the sacral roots may, in fact, modulate external sphincter function and in turn inhibit detrusor activity as a normal reflex. These early discoveries created the platform for the current and

future concepts and technologies that are used for neurostimulation and neuromodulation.

NEUROPHYSIOLOGY OF ELECTRICAL STIMULATION FOR STORAGE AND EMPTYING DISORDERS

The exact mechanisms of how neuromodulation works are not completely understood, but several plausible theories with testable hypotheses are under investigation. Most are founded on the basic neurophysiologic mechanisms that result in the normal storage and emptying functions of the bladder. Although there is an expanding amount of information on our knowledge of micturition neurophysiology, as discussed in this chapter, in this section the specifics of the micturition pathway in relation to neuromodulation are addressed.

Normal detrusor function appears to be a sacral balance under suprasacral influences of the sympathetic and parasympathetic nervous systems and their respective abilities to maintain continence. The sympathetic tone, for the most part, is dominant for the majority of time and thus provides continence or storage of urine; the parasympathetic nervous system allows detrusor contractions for emptying of the bladder. Thus the micturition reflex pathway is activated by initial bladder afferent excitation that then results in a bladder efferent excitation leading to a detrusor muscle contraction. The acquired and unique ability to void volitionally is due to either negative feedback (inhibition of voiding) or positive feed-forward (induction of voiding) influences of supraspinal inputs from the pontine micturition center on this sacral micturition reflex pathway. Any loss of either central supraspinal inhibitory influences or increased sensitization of bladder afferent signaling can lead to unmasking of involuntary voiding. Therefore this has been proved only in animals and, by deference, relates then to humans. There may be primitive reflexes that reside within the spinal cord that can be “awakened” by somatic and afferent nerve stimulation and may have something to do with the mechanism of action of neuro-modulation (de Groat, 1975, 1976; de Groat and Ryall, 1968a, 1968b). In patients with overactive bladder (OAB), some of the abnormal voiding reflex may be blocked with neuromodulation (impulse to pontine micturition center), thereby restricting involuntary detrusor contractions and restoring more normal voiding patterns. This has been shown with positron emission tomography scanning (Blok, 2006).

Bladder afferent nerve signaling sends information about pain and bladder fullness to the brain that will in turn initiate the micturition reflex. Bladder overactivity may be in part mediated by the loss of voluntary control of the voiding reflex and, furthermore, emergence of primitive voiding reflexes. In certain states of neurologic or inflammatory disease of the bladder, the previously silent C fibers may emerge and trigger the micturition reflex. Accordingly, blockade of this pathway by electrical neuro-modulation, similar to pharmacologic blockade by capsaicin (a C-fiber blocker), may suppress detrusor overactivity (DO) (Maggi and Meli, 1988; Chen et al, 1993).

Reflexes That Promote Bladder Storage

Two reflexes may play an important role in modulation of bladder function: the guarding reflex and the bladder afferent loop reflex. Both reflexes promote urine storage (guarding reflex under somatic influence and bladder loop reflex under sympathetic tone). The guarding reflex guards or prevents urine loss from times of cough or other physical stress that would normally trigger a micturition episode. Suprapontine input from the brain turns off the guarding reflex during micturition to allow efficient and complete emptying. The bladder afferent reflex works through sacral interneurons that then activate storage through pudendal nerve efferent pathways directed toward the urethral sphincter. Thus the activity has truly been realized only in cats but has been postulated to exist in humans and to function the same. Similar to the

Figure 81-1. The guarding reflex promotes continence and allows the outlet to contract the urinary sphincter during periods of stress (e.g., cough). The brain can turn this reflex off during voiding. (Modified from Leng WW, Chancellor MB. How sacral nerve stimulation neuromodulation works. *Urol Clin North Am* 2005;32:11–8.)

guarding reflex, the bladder afferent reflex promotes continence during periods of bladder filling and is quiet during micturition (Fig. 81-1).

Reflexes That Promote Bladder Emptying

Signals from the bladder that may modulate the need to void with fullness, pain, pressure, or stretch may elicit bladder afferent activity through the A δ or even C fibers. These bladder afferent nerve fibers then synapse with both parasympathetic efferents (bladder-bladder reflex) and parasympathetic urethral efferents (bladder-urethral reflex). The urge to void may then be translated as an initial activity (inhibitory) of the bladder-urethral reflex to allow the pressure in the urethral outlet to drop immediately before a bladder contraction ensues and simultaneously permit the bladder-bladder reflex to allow a smooth bladder contraction to occur as the reflex is maintained throughout the entire void (de Groat, 1978; de Groat et al, 1981, 1996).

Putative Mechanism of Action of Sacral Neuromodulation

Although our knowledge of how neuromodulation works is evolving, two main theories exist: (1) Direct activation of efferent fibers to the striated urethral sphincter reflexively causes detrusor relaxation and (2) selective activation of afferent fibers causes inhibition at spinal and supraspinal levels. Accumulating evidence suggests that activation of somatic sacral afferent inflow at the sacral root level that in turn affects the storage and emptying reflexes in the bladder and central nervous system accounts for the positive effects of neuromodulation on both storage and emptying functions of the bladder (Yoshimura and de Groat, 1992, 1997; Leng and Chancellor, 2005). Malaguti and coworkers (2003), using detection of somatosensory evoked potentials during sacral neuromodulation, concluded that sacral neuromodulation therapy works by sacral afferent activity and concomitant activation of the somatosensory cortex. Because sacral neuromodulation has been clinically proved for both storage (urgency/frequency and urgency urinary incontinence) and emptying (nonobstructive urinary retention) dysfunctions of the bladder, isolating the mechanism of action to the micturition reflex pathway of sacral afferent and efferent pathways alone is challenging. However, by understanding the reflexes that influence the promotion of urine storage or emptying of the sacral micturition reflex pathway one begins to realize how neuro-

Figure 81-2. Pudendal nerve afferent firing can modulate and accordingly inhibit the bladder micturition reflex. SNS, sacral nerve stimulation. (Modified from Leng WW, Chancellor MB. How sacral nerve stimulation neuromodulation works. *Urol Clin North Am* 2005; 32:11–8.)

modulation may affect these reflexes and elicit symptomatic and functional improvement of voiding function (Fowler et al, 2000). Animal models of sacral neuromodulation for DO are now being developed and may shed more light on how this technology achieves its benefits (Riazimand and Mense, 2004; Vignes et al, 2009).

Putative Mechanism of Action of Sacral Neuromodulation in Overactive Bladder

The bladder storage and emptying reflexes are modulated by several centers in the brain and may be altered by neurologic injury that effectively unmasks involuntary bladder contractions. Thus sacral neuromodulation of these primitive reflexes may restore normal micturition (de Groat, 1976). Animal data exist to support the fact that somatic afferent input to the spinal cord can affect the guarding and bladder-bladder reflexes (de Groat, 1978; Chen et al, 1993). It is believed that suppression of interneuronal transmission in the bladder reflex pathway may be how sacral neuromodulation affects DO (de Groat, 1976; Kruse and de Groat, 1993; Leng and Chancellor, 2005). The inhibition by electrical neuromodulation may, in part, modulate the sensory outflow from the bladder through the ascending pathways to the pontine micturition center, thereby preventing involuntary contractions by modulating the micturition reflex circuit but allowing voluntary voiding to occur (Fig. 81-2). The preservation of voluntary voiding may be due to selective avoidance of normal sensory ascending outflow pathways of the bladder from A δ fibers to the pontine micturition center as well as initiation of the descending pathways from the pontine micturition center to sacral efferent outflow pathways. Therefore, as is seen in clinical practice, sacral neuromodulation may affect and improve the abnormal bladder sensations, involuntary voids, and detrusor contractions but still maintain normal bladder sensations and voluntary voiding patterns.

Putative Mechanism of Action of Sacral Neuromodulation in Urinary Retention

Sphincteric activity can be turned off by brain pathways to allow efficient and complete bladder emptying. If the suprasacral pathways are altered, the guarding and urethral reflexes still exist and cannot be turned off. This may cause retention, as in the spinal

Figure 81-3. In neurologic disease the supraspinal circuitry is “disconnected” and therefore cannot turn off the spinal guarding reflex, and thus retention occurs. Sacral neuromodulation (SNS) can restore the normal voluntary pattern of micturition by inhibition of the spinal guarding reflex. (Modified from Leng WW, Chancellor MB. How sacral nerve stimulation neuromodulation works. *Urol Clin North Am* 2005; 32:11–8.)

cord-injured patient who in turn has detrusor-sphincter dyssynergia resulting in urinary retention. Thus inhibition of the guarding reflexes may allow urinary retention states to be improved (Fig. 81-3). Originally for urinary retention resulting from functional outlet obstruction, sacral neuromodulation was thought to directly turn off excitatory flow to the urethral outlet and facilitate bladder emptying. This may be an efferent effect of the primary afferent mechanism of sacral neuromodulation as reported by Dasgupta and colleagues (2005), who described novel neuroimaging evidence for the existence of abnormal interaction between the brainstem and cortical centers in women with urinary retention resulting from Fowler syndrome or overactive sphincteric activity. The direct therapeutic effect of sacral neuromodulation in patients with sphincter overactivity or functional outlet obstruction appears to be in the afferent restoration of a normal pattern of midbrain activity and decreased cortical activity leading to inhibition of the guarding reflexes.

ELECTRICAL STIMULATION FOR STORAGE DISORDERS

Criteria for Selection of Patients

Because many LUTS and LUTD are secondary to a neuromuscular cause, a thorough history and physical examination often will reveal the nature (acute vs. chronic) and help classify the cause (neurogenic, anatomic, postsurgical, functional, inflammatory, or idiopathic). In addition to the unique evaluation of pelvic floor muscle dysfunction (Siegel, 2005), a urinalysis is routinely performed; urine cytologic evaluation should be considered in patients who present with refractory symptoms of dysuria, urgency, or frequency of urination, because carcinoma in situ and bladder tumors may manifest as irritative bladder symptoms without hematuria. Further assessment of the bladder function, urodynamic studies including cystometrography, pressure-flow studies, and electromyography of sphincters and pelvic floor muscles are performed on a selected basis, because most non-neurogenic assessments are completed routinely with the use of a voiding diary and a focused physical examination of the pelvis. Electromyography is recommended in suspected cases of neurogenic bladder dysfunction, detrusor-sphincter dyssynergia, or Fowler syndrome and may be considered for evaluation of inappropriate pelvic floor muscle behavior (Dasgupta and Fowler, 2003). As of now, urodynamics

have not yielded adequate predictive factors that allow enhanced selection for patients undergoing sacral neuromodulation (Groenendijk et al, 2007). The characteristics of neurogenic bladders, as seen in patients with multiple sclerosis (MS) and spinal cord injury (SCI), can change with time and disease progression. Therefore re-evaluation with urodynamics and assessment of the upper urinary tracts may be needed when symptoms change despite active medical intervention.

Cystourethroscopy may yield information helpful in making a diagnosis. Anatomic lesions such as urethral stricture, bladder neck fibrosis, trabeculation, and bladder lesions have been found even in women with bladder outlet obstruction. Baseline upper tract imaging is performed in patients with neurologic disease or, if indicated, by physical or baseline studies or a patient's history.

Sacral neuromodulation is frequently attempted in patients in whom traditional conservative measures (e.g., bladder retraining, pelvic floor biofeedback, and medications) have failed and before more invasive surgical procedures (e.g., enterocystoplasty and urinary diversion). Despite all the studies done to date there are no defined preclinical factors, such as urodynamic findings, that can predict which patients will or will not respond to sacral neuromodulation.

Although most patients are considered candidates for neurostimulation and neuromodulation therapies when more conservative treatment has failed, there are some clinical considerations for excluding patients from this therapy. These include significant anatomic abnormalities in the spine or sacrum that may present challenges to gaining access; mental incapacitation of patients who cannot manage their device or judge the clinical outcome; physical limitations that prevent the patient from achieving normal pelvic organ function, such as functional urinary incontinence; and noncompliance of the patient.

Relative contraindications for patients who may be considering or who have an implantable electrical stimulation device are magnetic resonance imaging (MRI) and pregnancy. Magnetic fields produce currents in neuroelectrodes, and there is some concern that the magnetic field from MRI may damage the pulse generator, as discussed later. Many radiologists are reluctant to provide MRI services for patients with implantable electrical stimulation devices despite the anecdotal evidence that no adverse event has occurred when MRI has inadvertently or purposefully been done for emergent reasons or in small trials (Hassouna and Elkeline, 2005; Chermansky et al, 2011). For patients who have InterStim devices in place (see later), we advocate removal of the device in preparation for elective MRI based on current manufacturer recommendations. After the MRI procedure, a new neuroelectrode and generator may be placed. Anecdotal reports of patients safely undergoing the study (MRI) with the InterStim (Medtronic, Minneapolis, MN) implant in place have occurred, but patients should have the devices turned off in anticipation. Recent changes in the manufacturer recommendations do allow for head MRI to be performed with an InterStim in situ, but clearance requires several factors, including having the device turned off and use of a 1.5-Tesla magnet or lower (Medtronic models 3058 and select 3023; see manufacturer website for more information). Because of the potential for teratogenicity or abortion from the effect of electrical stimulation, it has been considered contraindicated in pregnant women with various voiding dysfunctions. However, whether electrical stimulation can cause abortion or malformation is not known. Wang and Hassouna (1999) reported no adverse effects of electrical stimulation on pregnant rats, and that termination of pregnancy is not advised for prospective mothers when electrical stimulation has been performed unknowingly in early pregnancy. Women with electrical stimulation devices for pelvic health conditions who become pregnant may simply turn off their devices during pregnancy.

Electrical Stimulation of the Bladder

Transurethral electrical bladder stimulation (TEBS) has been pursued not only for initiating sensory awareness of bladder filling and stimulating detrusor contractility (see later section) but also

for increasing bladder capacity at low pressure in pediatric patients with myelomeningocele (Kaplan et al, 1989; Decter et al, 1994). The authors in these two cited references carried on an interesting point-counterpoint discussion in publications regarding the practical benefit of TEBS (Decter, 2000; Kaplan, 2000), which remains controversial.

Both authors seem to be saying the same thing with respect to results but attach a totally different significance to the practical implications of the results. Kaplan (2000) points out that when the procedure was initiated the goal was to provide children with neurogenic bladder dysfunction, mostly secondary to spina bifida, enough sensation to detect a filling or full bladder and to have them synergistically void or catheterize in a timely manner. As the results of treatment have been evaluated over the years, the real benefit of this program, to Kaplan at least, was the potential to increase bladder capacity while maintaining or decreasing end-filling bladder pressure (in essence, improving compliance). Decter (2000) gives what seems to be a reasonable summation of the largest multi-institutional report of this therapy involving 568 patients who underwent TEBS at 11 institutions, only 335 of whom had adequate pretreatment and post-treatment urodynamics for evaluation. Bladder capacity increased by 20% or more in 56% of the 335 patients, whereas pressure at bladder capacity decreased by 25% or more in 16% of those in whom the bladder capacity increased. Decter (2000) calculated that only 30 of 335 patients had both a 20% or more increase in bladder capacity and a 25% decrease in compliance. He reports his experience with 25 patients during a 4-year period as showing that bladder capacity increased more than 20% (values referred to a comparison to age-adjusted bladder capacity) and end-filling bladder pressures showed clinically significant decreases in 29% of patients. Putting this in perspective, he believes "the practical benefits our patients derive seem limited . . . the urodynamic improvements we achieved after stimulation did not materially alter daily voiding routine (i.e., clean intermittent catheterization) of these children." Pugach and associates (2000) also reported the results of TEBS in a group of pediatric patients; only 7 of 44 (16%) had safe storage pressures with continence after treatment. Data have been limited since 2000 on this treatment modality, probably owing to targeting of other nerves with better potential.

Sacral Rhizotomy

In most cases, bilateral anterior and posterior sacral rhizotomy or conusectomy converts an overactive detrusor to an areflexic one. This alone may be inappropriate therapy because it also adversely affects the rectum, anal and urethral sphincters, sexual function, and the lower extremities. In an attempt to leave sphincter and sexual function intact, selective motor nerve section was originally introduced as a treatment to increase bladder capacity by abolishing only the motor supply responsible for involuntary contractions. The initial use of this procedure followed the observation that the third anterior (ventral) sacral root provided the dominant motor innervation of the human bladder. To enhance the clinical response and minimize side effects, differential sacral rhizotomy always should be preceded by stimulation and blockade of the individual sacral roots with cystometric and sphincterometric control.

Although technique refinements, such as percutaneous radiofrequency selective sacral rhizotomy and cryoneurolysis, have occurred, there is still controversy about the role of anterior rhizotomy procedures within a treatment plan for DO. Torrens (1985) summarized successful results in collected groups of patients that ranged from 48% for idiopathic overactivity to 81% for patients classified as having a "paraplegic bladder." However, as he astutely pointed out, the definition of success varies across series and from one patient to another. When these procedures are used, they should certainly be preceded by urodynamics and urologic evaluation of the effects of selective nerve blocks before performance, especially in patients without fixed neurologic disease or injury. Even then, unintended effects on pelvic and lower extremity sensory or

motor functions may occur with disastrous medical and legal sequelae.

Tanagho and Schmidt (1988, 1989) and Brindley and Rushton (1990) have popularized the concept of sensory deafferentation by dorsal or posterior rhizotomy to increase bladder capacity as part of their overall plan to simultaneously rehabilitate storage and emptying problems in patients with significant SCI or disease. These are patients in whom electrical stimulation also was used to alleviate emptying deficits (see section on emptying disorders). McGuire and Savastano (1984) also mentioned dorsal root gangliectomy alone in such patients to increase bladder capacity.

Gasparini and colleagues (1992) reported durability of the deafferentation response to selective dorsal sacral rhizotomy up to 64 months after section. The technique involves selecting nerve roots whose intraoperative stimulation provokes an adequate detrusor response. The dorsal and ventral components of these roots are then separated and the dorsal root or roots severed. An increase in bladder capacity of 259 to 377 mL was noted in 16 of 17 patients studied (24 in the original series), with an increase in the volume to the first contraction of 99 to 270 mL. Of the patients, 14 were cured of incontinence and 2 improved; the technique failed in 1 patient. Of 7 potent men, 2 experienced a decrease in erectile frequency but were still able to achieve penetration. Bowel and sphincter function were unaffected. Koldewijn and associates (1994) reported on the effects of intradural bilateral posterior root rhizotomies from S2 to S5 with implantation of an anterior root stimulator in a group of patients with suprasacral SCI. All showed persistent detrusor areflexia afterward, although 2 required subsequent secondary rhizotomy at the level of the conus. A majority showed decreased bladder compliance up to 5 days postoperatively, followed by a rapid increase thereafter.

Brindley (1994) summarized the advantages of bilateral posterior sacral rhizotomy in treatment of voiding dysfunction after SCI as abolishing reflex incontinence, improving compliance, and abolishing striated sphincter dyssynergia without altering resting tone. Partial or selective procedures are considered only in such patients who retain some sensation or have excellent reflex erections. Madersbacher (2000) comments that posterior sacral rhizotomy for sacral deafferentation of the bladder is best achieved by the intradural approach, which has the advantage that, in this location, motor and sensory fibers easily can be separated, whereas distal to the spinal ganglion, motor and sensory fibers are intermingled and a clear separation is no longer possible. If an intradural procedure is not possible, he believes that a deafferentation at the level of the conus medullaris is preferable to an extradural sacral approach. He mentions that he has treated 65 tetraplegic or paraplegic patients with post-SCI reflex urinary incontinence who were resistant to all other means of conservative treatment. Incontinence was abolished in 90% of these patients.

Sacral Neuromodulation

Neuromodulation is an innovative treatment of LUTS and LUTD of bladder storage secondary to neuromuscular causes. In addition to the application of evolving technologies for sacral neuromodulation therapy, expanding clinical indications such as neurogenic DO, post-sling-related voiding dysfunction, interstitial cystitis, pelvic pain, pediatric voiding dysfunction, and bowel disorders, as well as novel forms of transcutaneous and implantable neuromodulation devices for different nerve roots are under investigation.

Technique

Sacral nerve stimulation (SNS) by the InterStim procedure is performed in two stages: stage I, a clinical trial of a temporary or permanent lead for external stimulation, and stage II, implantation of a subcutaneous implantable pulse generator (IPG). Each stage can be performed with monitored anesthesia care supplemented by local anesthesia. During the initial introduction of sacral neuromodulation therapy, patients underwent a percutaneous nerve

evaluation by the placement of a unilateral percutaneous lead into the S3 foramen with use of local injectable anesthesia. The lead was connected to an external pulse generator and worn by the patient for several days. A large number of false-negative results with therapy are attributed to improper lead placement and migration. Whereas some physicians still prefer to perform the first stage by a percutaneous nerve evaluation approach, many have adopted a permanent tined lead placement for the first stage in an attempt to avoid the issues related to high false-negative results (migrated lead so as to have a suboptimal test phase) with the first stage and high false-positive results (did the lead work or is it implanted for the wrong reason with true failure) with the second stage. Changes in LUTS and postvoid residuals (PVRs) are recorded in a detailed bladder diary. If improvement is minimal or absent, revision or bilateral percutaneous lead placement may be attempted. If greater than 50% improvement in symptoms of urgency/frequency or urgency urinary incontinence is attained, a permanent IPG is implanted. The length of the trial with the external pulse generator may vary slightly from patient to patient, by the indication, and by the surgeon's practice preference. In patients with urgency/frequency and urgency urinary incontinence, a 1- to 2-week trial is generally adequate. For retention, a longer trial of 3 to 4 weeks or more may be necessary before a desired clinical response is obtained.

Previous lead placement required a more time-consuming surgical dissection of the layers above the sacral foramen and unreliable lead fixation with anchors. Recent technical advances have made implantation of the percutaneous lead easier and less prone to migration. Spinelli and colleagues (2003) were the first to present the advantages of the **tined lead** that used a percutaneous approach for placement and fixation (Fig. 81-4). Subsequent large-scale clinical experience worldwide confirms that the tined lead is less prone to migration and has decreased false-negative results with the screening trial. Furthermore, the false-positive rate of the screening trial is reduced when placement of a permanent lead with reliable fixation during the screening trial ensures that the same location of stimulation is achieved when the IPG is implanted. With a percutaneous nerve evaluation or similar temporary lead electrode during the screening trial, a different clinical outcome may occur when the permanent lead is placed at the time of the IPG implantation.

For the **first stage** of the procedure, preoperative intravenous antibiotics are given before the procedure and aseptic techniques of foreign body implants are implemented. At present, no defined antibiotic regimen is agreed upon and is left to surgeon discretion (preoperatively or postoperatively). The patient is placed in the prone position, and the buttocks are held apart by wide tape retraction so that the anus is visible during test stimulation. The anus and tape are prepared in a sterile fashion and then covered with a sepa-

Figure 81-4. The tined lead is introduced typically into the S3 nerve foramen. The tines allow the lead to be fixed into the fascial layers above the sacrum. This lead has a quadripolar configuration (four contact points). (Courtesy Medtronic, Minneapolis, MN.)

rate plastic drape until visualization is needed during the procedure. The sterile drape covering the feet must be folded back such that the feet can be visualized during the procedure as well.

The location of the S3 foramen is approximated by measuring 9 cm cephalad to the drop-off of the sacrum and 1 to 2 cm lateral to the midline on either side. Alternatively, the site may be localized by palpating the cephalad portions of the sciatic notches bilaterally and drawing a connecting line that intersects the midline of the sacrum; one fingerbreadth on either side of the midline of the sacrum at this intersection will define the location of the S3 foramen (Fig. 81-5). The foramen needle is then inserted into the S3 foramen with a slight medial to lateral angulation to mimic the course of the nerve as it exits the foramen. The pelvic plexus and pudendal nerve run alongside the pelvis, and therefore the needle should be placed just inside the ventral foramen. The position of the needle is confirmed by fluoroscopy. The nerve is tested for the appropriate motor response, which is dorsiflexion of the great toe and bellows contraction of the perineal area, which represents contraction of the levator muscles (bellows reflex). Simultaneous sensory responses determined at the time of lead placement help optimize positioning. Although this is controversial, if one can localize the stimulation at the time of lead positioning to the vagina-rectum juncture in females and perineoscrotal area in males, this is proper localization of the device. The foramen needle stylet is then removed and

Figure 81-5. A, The percutaneous test stimulation is performed in an outpatient setting. A small lead wire is placed into S3 and connected to an external stimulator for 1 week to administer stimulation to the nerve roots. B, Measurement of the S3 nerve foramen is typically 9 cm to the coccyx and 11 cm to the anal verge. To find the rough site of the S3 nerve foramen 1 to 2 cm lateral to this mark is measured. The “cross hair” technique can be used to find the midline fluoroscopically and the lower aspect of the sacroiliac joints laterally to find the S3 nerve foramen, as well. (Courtesy Medtronic, Minneapolis, MN.)

Figure 81-6. Fluoroscopy is used to confirm lead placement, typically with the lead configurations to obtain optimal muscle (bellows response and ipsilateral toe contractions) and sensory (vaginal, penile, or scrotal “pulsating” feeling) responses. The lead then may be deployed.

Figure 81-7. A 3- to 4-cm counterincision in the upper gluteal crease is made for a deep subcutaneous pocket to allow implantation of the implantable pulse generator.

replaced with the introducer sheath. The distal aspect of the lead consists of four electrodes numbered 0 through 3. The lead is placed into the introducer sheath as directed to expose the electrodes. Typically, electrodes are positioned such that electrodes 2 and 3 straddle the ventral surface of the sacrum (Fig. 81-6). Test stimulation is repeated on each electrode, and the responses are observed. An S3 response should be noted on at least two of the electrodes (see Table 81-2). Once the surgeon is satisfied with the position, the sheath is removed, releasing the tines that anchor the lead. If the lead is placed too deep, the tines reside within the sacral foramen and removal (if and when necessary) becomes more challenging. A sensory response, sensation of stimulation in the perineum, is not needed to confirm proper placement if the correct S3 motor response is observed, although this is debatable. However, when a motor response is absent, raising the conscious level of the patient during the procedure and detecting the correct sensory response will confirm proper localization and a clinical response may still be obtained during the screening trial period despite the absence of the motor response.

A 3- to 4-cm incision into the subcutaneous tissues in the upper lateral buttock is made below the beltline or below the level of the ischial wings for connecting the permanent lead to the percutaneous extension lead wire. If the screening trial is successful, this connection site will be the site of implantation for the IPG. With use of the tunneling device provided in the commercial kit, the permanent lead is transferred to the medial aspect of the lateral buttock incision. The lead is then connected to the extension wire, and the tunneling device is used again to transpose the extension wire from the medial aspect of the incision to an exit point on the contralateral side of the back. This transfer and long tunnel reduce the occurrence of infection from the percutaneous exit site of the wire. The extension wire is connected to the external pulse generator. Patients are able to resume their normal activities immediately but are advised to limit excessive movement-related activities, such as high-impact exercises, for the duration of the trial period.

The external generator can be flexibly programmed for the duration of the intended trial while the patient records symptoms and bladder function in a voiding diary. Initial programming should be performed to maximize patient comfort and attempt to localize sensory response to the vaginal or perineoscrotal areas with a gentle pulsating feeling. If there is more than 50% improvement in the symptoms or voiding function, a stage II procedure is performed.

A stage II procedure entails placement of the IPG. No fluoroscopy is required during stage II when a permanent neuroelectrode has been placed for the stage I procedure; however, if a percutane-

ous nerve evaluation was performed for stage I, fluoroscopic confirmation of the neuroelectrode placement is advised. The patient may be placed in the prone position or a lateral position with the site of the previous lateral incision for the lead connections placed upward (Fig. 81-7). The lateral position may improve ventilation during sedation. The previous buttock incision overlying the lead connections is opened, the percutaneous extension wire is removed, and the extension lead is secured to the permanent lead and subsequently to the IPG. Copious irrigation and antibiotic solution is often used to minimize IPG infections. A pocket is made in the subcutaneous tissue that is large enough to avoid tension on closure and at a depth to provide a covering layer of subcutaneous tissue anterior to the pulse generator to prevent erosion.

Outcomes

Urinary urgency, frequency, and urgency incontinence have a significant impact on medical health and quality of life. Neuromodulation offers an alternative to patients who may be considering irreversible surgical options when pelvic floor muscle reeducation and pharmacologic therapy have failed. Outcomes of SNS for the indications of idiopathic urgency/frequency and urgency urinary incontinence are derived from only two studies that have randomized patients to active or delayed therapy as well as reports from numerous prospective and retrospective reviews of case series and registry databases.

Schmidt and coworkers (1999) reported on SNS therapy in 76 patients with refractory urgency urinary incontinence from 16 centers worldwide randomized to active or delayed therapy (control group) during the study period of 6 months. Of the 34 patients receiving active SNS therapy compared with the delayed group, 16 (47%) were completely dry and an additional 10 (29%) demonstrated more than 50% reduction in incontinence episodes. Complications were IPG site pain in 16%, implant infections in 19%, and lead migration in 7%.

In a similar study design, Hassouna and colleagues (2000) reported the outcomes of SNS on refractory urgency/frequency conditions in 51 patients randomized from 12 centers during an initial 6-month period that was extended to 2 years. Outcomes at 6 months in the active SNS group showed improvement in the number of daily voids (16.9 ± 9.7 to 9.3 ± 5.1), volume voided (118 ± 74 mL to 226 ± 124 mL), degree of urgency (rank score of 2.2 ± 0.6 to 1.6 ± 0.9), and SF-36 quality-of-life measures. At 6 months after implantation, stimulators in the active group were turned off and urinary symptoms returned to baseline values. After reactivation of SNS, sustained efficacy was documented at 12 and 24 months.

Limited but conformational results of the earlier randomized trials have been obtained from prospective series (Shaker and Hassouna, 1998; Siegel et al, 2000; Janknegt et al, 2001; Marcelissen et al, 2010; Al-zahrani et al, 2011) and registry studies (Spinelli et al, 2001; Hedlund et al, 2002) evaluating efficacy, safety, and quality-of-life measures. The results for the registration trial that led to approval by the U.S. Food and Drug Administration (FDA) for SNS (Pettit et al, 2002) reveal that 37 of 62 patients (60%) with refractory urgency/frequency or urgency urinary incontinence achieved an improvement of 50% or more in their condition. van Kerrebroeck and coworkers (2007) reported on a 5-year prospective worldwide series for patients with the InterStim device for varying indications and for the urgency/frequency and urgency urinary incontinence populations, and good success was achieved in all groups. Of note is that the analysis included patients in the initial registration trial who then “crossed over” to the prospective 5-year trial. This study, unfortunately, was influenced by several patients who did not attend all follow-up visits and, therefore, had missing data points, a problem reflective of this challenging subgroup. Outcomes data were based on “last observation carried forward,” which is of concern for not being statistically optimal, but nonetheless these are still the longest term data available for this technology. Separate analysis with intent-to-treat models do still show these data to be conclusive of good long-term efficacy, albeit lower than the last observation carried forward. Some have tried to push the success rate or improvement percentage beyond 50% up to 70% in an attempt to get a true test and minimize any placebo phenomenon (Amend et al, 2013). This same trial also extended the stage I lead phase up to 6 weeks again to minimize placebo rates and interestingly did not show higher infection rates, although their patients were admitted to the hospital for antibiotics for longer than is done in other parts of the world.

Another impactful trial underway in the United States is prospectively evaluating sacral neuromodulation with 200 units of onabotulinumtoxinA (OBTX) in a randomized fashion in patients with idiopathic OAB. Another study compares InterStim with standard medical therapy in a randomized fashion (Siegel et al, 2015).

Special Populations

With the success of neuromodulatory therapies for refractory DO and urinary retention, it should be no surprise that indications are expanding. Despite the fact that there is no true FDA-approved indication for neuromodulation in select populations, these groups all have some component of the indicated symptom complex that includes urgency, frequency, urgency urinary incontinence, or urinary retention. The current (not FDA approved) expansion of indications for neuromodulation has developed into areas of neurogenic bladder (Parkinson disease, MS, SCI), interstitial cystitis (painful bladder syndrome), pelvic pain, and pediatric voiding dysfunction. Both fecal incontinence and bowel emptying disorders were formerly classified in this group; however, fecal incontinence is now FDA approved and represents a large growing area of implantation because of high success rates for this indication.

Neurogenic Bladder. Patients with neurogenic bladder may have several urodynamic events that lead to their symptomatic voiding dysfunction. This may include neurogenic DO, detrusor-sphincter dyssynergia, and flaccid areflexia. Whereas neuromodulation has not been well examined in cases of obvious areflexia (possibly because of the need for some end-organ response for neuromodulation to have any benefit), it has been studied in small subgroups of patients with DO and possibly detrusor-external sphincter dyssynergia, although few published reports exist.

Because the spectrum of neurologic diseases with potential bladder manifestations is wide, one must be cognizant of a few important relative contraindications before contemplating current neuromodulatory therapies, as follows: Significant bone abnormalities in the spine or sacrum that may present challenges to gaining access, mental incapacity of patients who cannot manage the device, physical limitations that prevent voiding

(functional incontinence), future need of MRI (nonbrain only), and noncompliance.

Multiple Sclerosis. MS is a chronic demyelinating disease of the central and peripheral nervous system that can cause a variety of voiding dysfunction scenarios, including neurogenic DO, detrusor-sphincter dyssynergia, areflexia, and combinations of these. Because many patients have been refractory to standard therapies, neuromodulation or neurostimulation (to be addressed later in the section on neurostimulation for retention) may be considered a part of their treatment options. In an appropriately selected patient with MS, neuromodulation truly has some promise because it may balance the function of the bladder, as well as that of the outlet (two of the main components of MS-related voiding dysfunction). This may be considered off-label use of neuromodulation because it is not approved specifically for MS-related voiding dysfunction, but approval may be based on symptoms such as urgency, frequency, or often urgency urinary incontinence and even nonobstructive urinary retention.

No prospective randomized trials exist on the use of neuromodulation in management of MS-related bladder dysfunction. Small series with encouraging results in patients with MS demonstrate that neuromodulation may have a role in treatment of MS-related voiding dysfunction (Bosch and Groen, 1996; Wallace et al, 2007; Minardi and Muzzonigro, 2012; Peeters et al, 2014). It appears that the best candidates are ones with mild, nonprogressive MS, with few functional issues, who also have DO or even retention but not areflexia. One of the major issues that arises in the patient with MS in particular is the potential change in the disease state that may be potentiated by neuromodulation. Although this may be theoretical, it was one of the factors cited by the FDA in the original sacral neuromodulation trials and precluded MS patients from being enrolled (Hassouna et al, 2000).

A secondary issue that may arise if a patient with MS is implanted with the lead and IPG system is the potential need for MRI in the future. One should maintain close contact with the patient's neurologist as to the decision to place a neuromodulatory device to prevent any future need for MRI or selection of a patient in an active phase of disease who requires routine MRI. The main concern with MRI and implantable stimulator or pacemaker-type devices is that heating of the leads has been demonstrated in vivo and in vitro (Roguin et al, 2004; Martin, 2005). Whereas some question the clinical significance of the small temperature changes with the leads, the potential exists to elicit nerve damage with heating of the lead and the magnetic field may change the generator itself (Gimbel and Kanal, 2004). As previously mentioned, the recent manufacturer change to allow head MRI has been helpful in this patient population to have InterStim placed. At present though, it is contraindicated to perform MRI of a patient with an implantable neurostimulator system, if the MRI is looking at spinal cord segments or anything below the head.

Spinal Cord Injury. Many specialists who treat neurogenic disorders resulting from SCI realize that a patient may present with a variety of clinical and urodynamic findings. Many patients have neurogenic detrusor areflexic situations, but perhaps more often and sometimes more challenging is the subset who may be incontinent from neurogenic DO with or without concomitant sphincter dyssynergia. Furthermore, the adverse sequelae of treated or untreated SCI may include infections, urolithiasis, reflux, or obstruction. The goal, then, is not only to prevent these adverse events but also to ensure a bladder that functions well, empties at a low pressure to protect the upper tracts, and maintains a good capacity and continence. Whereas it is implied that an intact reflex arc should be in place for neuromodulation to work, this has not been proved in clinical studies. Basic science data suggest that at least some communication should exist between sacral outflow and the pontine micturition center to allow processing for the reflexes that may be inhibited by the brain (de Groat et al, 1981). Thus a patient with a complete spinal cord lesion may not have the same potential benefit from neuromodulation as does one with an incomplete lesion. Again, this fact has yet to be proved clinically in patients. Shaker and colleagues (2000) described their observations

in a group of female rats that developed OAB 3 weeks after spinal cord transection, associated with an increase in neuropeptide content of the dorsal root ganglion of L6. The spinal cord transections were at level T10. Electrostimulation of S1 was carried out and abolished overactivity while still attaining the rise in neuropeptide content in the L6 dorsal root ganglion. This suggested that blockade of C-fiber afferent pathways may have been one of the mechanisms of action of neuromodulation of the sacral root. In addition, they believed the time course of the reduction in neuropeptide content may explain the long-term changes that occur with chronic neuromodulation and the time needed for DO to return toward baseline after neuromodulation is initiated.

From a clinical perspective, few studies exist in neurogenic patients alone for whom sacral neuromodulation was performed. [Andrews and Reynard \(2003\)](#) described a patient with T8 paraplegia with residual urinary urgency and urgency urinary incontinence who underwent percutaneous tibial nerve stimulation (see later section in this chapter) for his problem. This patient experienced an almost twofold increase in bladder capacity; this was repeated, and again increased cystometric capacity was demonstrated on follow-up. Patients with incomplete SCI may respond in a fashion similar to that of the remainder of the population, with fairly high success rates in motivated individuals ([Lombardi and Del Popolo, 2010](#); [Peeters et al, 2014](#)).

It is clear that this is an emerging area of interest in current techniques, and some have postulated a role for selective stimulation in neurogenic patients as a means to achieve better results. Future research will clearly need to be done in this challenging subset of patients.

Voiding Dysfunction after Prior Sling or Anti-Incontinence Surgery. It is well known that patients may develop urinary retention or some form of voiding dysfunction after vaginal sling surgery or other forms of surgical management for urinary incontinence. Whereas the mainstay of therapy is to surgically “undo” the operation, many patients who have been obstructed for some period may manifest long-term voiding difficulty. This problem may vary among urgency, frequency, urgency urinary incontinence, or continued problems with retention and incomplete emptying despite adequate urethrolysis. This patient population (when refractory symptoms continue) may be ideally suited to the placement of a sacral neuromodulation device ([Starkman et al, 2008](#)). After implantation, patients had improved quality-of-life scores, improved urgency and frequency scores, and diminished urgency urinary incontinence in a small retrospective series.

Interstitial Cystitis (Painful Bladder Syndrome). Chronic pelvic pain and interstitial cystitis are challenging and frustrating conditions for both the physician and the patient. Therapeutic options are limited and frequently ineffective. Whereas neuromodulation therapy in patients with interstitial cystitis has typically been reserved for patients considering major surgery (e.g., cystectomy and urinary diversion) when behavioral and pharmacologic therapies have failed, more innovative consideration has been given to earlier application of this therapy before chronic neuroplastic changes become irreversible.

Interstitial cystitis is not an FDA-approved indication for neuromodulation; however, the symptom complex of urinary urgency and frequency is well within the standard approved criteria. It may be realized that neuromodulation for interstitial cystitis may be best in combination with other therapies, because interstitial cystitis is thought to require a multimodal approach and neuromodulation should be considered only one part of the multimodal therapy. It is a later stage modality listed in the most recent interstitial cystitis guidelines that can be offered.

[Comiter \(2003\)](#) performed a prospective evaluation of 25 patients with refractory interstitial cystitis. Of the 25 patients, 17 demonstrated more than 50% improvement in average pain score and voiding symptoms and therefore qualified for permanent IPG placement. At a mean of 14 months of follow-up, improvements were seen in frequency, nocturia, and mean voided volume. Average pain scores decreased from 5.8 to 1.6 on a 10-point scale, and Interstitial Cystitis Symptom Index (ICSI) and Problem Index

(ICPI) scores decreased significantly. Furthermore, 94% of patients implanted had a sustained improvement in symptoms. Similar findings were noted by [Whitmore and associates \(2003\)](#) in 33 patients who had statistically improved parameters in frequency, pain, average voided volume, and maximum voided volume, as well as ICSI and ICPI scores.

[Peters and colleagues \(2003\)](#) retrospectively evaluated 21 patients with refractory interstitial cystitis with pelvic pain who underwent permanent implantation of the IPG. The patients were contacted by mail and asked to respond to a questionnaire that addressed the use of narcotic pain medication. There was an average decrease in morphine dose equivalents after implantation of 36%. In addition, patients were asked to rate their pelvic pain on a 7-point scale. Most patients reported a moderate-to-marked improvement in pain after sacral neuromodulation. Approximately one fourth of the patients were able to discontinue narcotics completely, and patients overall were satisfied with this form of therapy compared with previous ones.

[Chai and coworkers \(2000\)](#) reported that perhaps some of the effects of neuromodulation in patients with interstitial cystitis may be due to changes in antiproliferative factor. His group demonstrated that levels of antiproliferative factor and epidermal growth factor were elevated in the urine of patients with interstitial cystitis and that these levels subsequently normalized after a short trial of sacral neuromodulation.

Chronic Pelvic Pain. Pelvic pain, much like interstitial cystitis, has been investigated with therapy such as neuromodulation; again, this affects a challenging subset of patients who do not receive benefit from other treatments. [Bemelmans and associates \(1999\)](#) described the mechanism in pain inhibition as involving the gate control mechanism at the spinal segmental level. At this point, large somatic sensory fibers inhibit the activity in small A δ or unmyelinated C fibers via sacral segmental interneurons or perhaps supraspinally by way of the spinobulbospinal reflex system. The hypothesis is that sacral root stimulation for the treatment of many disorders may result from decreasing pelvic floor spasticity.

Multimodal therapy is likely to be of benefit; however, results may not be optimal in all cases. **Spinal cord stimulation at higher centers has been used by pain therapists and with moderate success; however, trial design and consistent entry criteria are debated** ([Feler, 2003](#); [Mailis-Gagnon et al, 2004](#)). Small series have looked at more selective stimulation, primarily at sacral roots. [Abouseif and colleagues \(2002\)](#) examined the effect of sacral neuromodulation on pelvic floor dysfunction in 41 of 64 patients thought to have chronic pelvic or perineal pain. Patients with chronic pelvic pain had decreased pain scores on average (5.8 to 3.7) after neuromodulation based on validated pain scales. [Siegel and associates \(2001\)](#) examined patients with intractable pelvic or genitourinary pain in the absence of neurologic or pelvic disease. Sacral neuromodulation did benefit patients, and they described a decrease in severity of pain and quality-of-life improvements. Bilateral caudal sacral stimulation may yield almost 40% improvement in pain scores in patients with mixed symptoms of voiding dysfunction and pelvic pain ([Zabihi et al, 2008](#)). Still, some form of placebo effect is likely to exist and is challenging to control in these small series.

Pediatric Voiding Dysfunction. Children often experience voiding dysfunction in fairly high rates and may in fact have refractory bladder problems that require advanced management schemes. Neuromodulation has been considered in this population because of the variety of LUTD that pediatric patients may have, including OAB, urinary retention, and non-neurogenic neurogenic bladder (the Hinman bladder syndrome). Because neuromodulation represents a minimally invasive option for refractory management, it follows that this may be an approach to be used in pediatric LUTD. Still, sacral neuromodulation is not approved by the FDA for use in pediatric patients, perhaps owing to lack of data on what the sacral lead would do with concomitant growth of the spinal cord, nerve roots, and foramina. Accordingly, efforts in the past have been centered on alternative means of delivering electrical stimulation to the bladder and pelvic floor in these patients. Few studies exist of pediatric patients and sacral

neuromodulation. [Guys and coworkers \(2004\)](#) prospectively examined 21 patients to 21 years of age with sacral neuromodulation in the setting of neurologic disease consisting predominantly of spina bifida. The neuromodulation implant group had improved compliance and bladder capacity at 6 and 9 months but not at 12 months. Of the 21 patients, 9 improved their intestinal transit times and 1 patient had complete disappearance of urinary incontinence. No patients in the control group experienced an improvement of their condition. [McGee and associates \(2009\)](#) described the use of an incisionless first- and second-stage sacral neuromodulation procedure with fairly high success rates in pediatric patients with dysfunctional elimination syndromes and had minimal complications.

Transcutaneous electrical nerve stimulation (TENS) has been used in pediatrics because it is noninvasive. Usually patch electrodes are placed on both sides of the S3 nerve foramen and connected to a pulse generator and amplifier. [Hoebeke and associates \(2001\)](#) reported on this use in 41 children. In this case series, patients had urodynamically proved DO and anticholinergic therapy had failed in all. Patients had daily therapy with the patch electrodes placed at S3, and stimulation was delivered at 2 Hz. A 76% response rate was observed, due in part to increase in bladder capacity and reduction in urgency urinary incontinence and urgency symptoms. Of 41 patients, 21 (51%) were definitively cured; the remainder experienced relapse in the ensuing 1 year of follow-up. [Bower and colleagues \(1998\)](#) reported a similar fairly high success rate with 17 children treated with S3 transcutaneous stimulation and demonstrated dryness in 73.3% of patients and improved urgency and bladder capacity based on visual analog scales and voiding diaries. A more recent study by [Malm-Buatsi and associates \(2007\)](#) also showed continued benefit in patients when 8 of 12 (75%) received statistically significant benefits when therapy was completed. Although this technology seems to have fairly good success, there has been no trial in a randomized prospective controlled fashion that may increase its acceptance.

Posterior tibial nerve stimulation (PTNS), much like TENS, has been studied in pediatric patients because of its lack of invasiveness. [DeGennaro and colleagues \(2004\)](#) reported on PTNS in children in a subset of patients with refractory non-neurogenic voiding dysfunction: 80% of patients had symptom improvement and 44% were totally dry; 62.5% had improvement in bladder capacity. Furthermore, 71% had improvement in urinary retention symptoms. No patients had significant problems from the therapy, and it was overall thought to be both safe and well tolerated. [Hoebeke and associates \(2002\)](#), in a pilot study of PTNS, demonstrated similar success with 32 children. Of the 28 children with urgency before therapy, the urgency disappeared after therapy in 7 and improved in 10. Of the 23 children with daytime incontinence before treatment, 4 became dry after stimulation and in 12 patients the incontinence decreased. Of the 19 patients who reported abnormal voiding frequency of either less than 4 or more than 8 voids per day, 16 of 19 achieved a normal frequency of 4 to 6 voids daily. [Barroso and associates \(2013\)](#) compared parasacral cutaneous neuromodulation with percutaneous tibial nerve stimulation and noted improved results with parasacral stimulation in a prospective nonrandomized study; however, despite improvements, they were not found to be statistically significant changes.

Fecal Incontinence and Bowel Disorders. Sacral neuromodulation was investigated for bowel disorders on the basis of some of the early experience in patients with bladder conditions who exhibited treatment benefits with regard to the bowel symptoms ([Pettit et al, 2002](#)). The use of sacral neuromodulation in bowel disorders has recently been approved for use in the United States and was predated for approval in many other parts of the world beforehand. The two major areas of interest with regard to neuromodulation and bowel disorders are fecal incontinence and constipation.

Fecal Incontinence. Several studies have been done to examine the utility of sacral neuromodulation in fecal incontinence ([Kenefick et al, 2002a, 2002b; Uludag et al, 2002; Melenhorst et al, 2007](#)). It appears that patients with a variety of causes of fecal incontinence seem to have benefited from sacral neuromodulation therapy in this

setting. The Cleveland Clinic scoring system allows comparisons to be made with regard to outcome measures, including incontinent episodes (solid, liquid, and flatus), pad use, and lifestyle changes. Several studies used this scoring system, and all have shown improvements in these assessed parameters ([Matzel et al, 2003; Jarrett et al, 2004](#)). Sacral stimulation has been shown to be more effective than medical management based on randomized controlled trials for fecal incontinence ([Tjandra et al, 2008](#)). The mean incontinent (fecal) episodes decreased from 9.5 per week to 3.1 ($P < .001$), and perfect continence was gained in 47.2%. Similar improvements were demonstrated in quality-of-life parameters. A recent long-term analysis demonstrated continued benefit for patients with fecal incontinence, with 89% of patients who were followed having more than 50% improvement and 36% being totally dry ([Hull et al, 2013](#)). The exact prognostic indicators for success have yet to be defined, particularly as they relate to the cause of the fecal incontinence (sphincter defect, neurologic, functional). Interestingly, even patients with 120-degree sphincter defects seem to exhibit good efficacy from this therapy. Overall, there is tremendous interest in neuromodulation for fecal incontinence. This has challenged the use of sphincteroplasty in many of these patients because the success for neuromodulation seems much higher than that of overlapping sphincter repairs.

Constipation. Constipation as such is a broad term, with the definition being in evolution. It is thought to be representative of difficult evacuation of feces and infrequent or inadequate defecation. Other refinements to the definition may include bowel frequency of fewer than three stools per week. The ROME II criteria categorize constipation into subtypes, including constipation-predominant irritable bowel syndrome, functional constipation, and pelvic floor dyssynergia ([Drossman and Corazziari, 2000](#)). Sacral neuromodulation has been examined in this regard and has had favorable results on the basis of some of the criteria listed for improvement. [Ganio and associates \(2001\)](#) described 16 patients who underwent permanent implantation of sacral leads for constipation whereby they had a more than 50% decrease in difficulty emptying the rectum and more than 80% improvement in the Cleveland Clinic constipation score that persisted during the course of 1 year of follow-up. Other series have shown similar improvements, although in smaller numbers ([Kenefick et al, 2002a, 2002b; Sharma et al, 2011](#)). Still, with the small series available, it is difficult to make any meaningful analyses. The more important parameters, perhaps, in this setting relate to quality of life; these have been assessed with SF-36 questionnaires and have proved to be beneficial at least in the study by Kenefick and associates. All of these results suggest, at least, that there is some benefit of sacral neuromodulation in refractory constipation cases. Further study is warranted to assess prognostic factors to better decide on future candidates for this therapy.

Bilateral Stimulation and Neuromodulation

The current technique for sacral neuromodulation involves a unilateral lead at the S3 nerve foramen to achieve results in cases of urgency, frequency, urgency urinary incontinence, and idiopathic nonobstructive urinary retention. Bilateral stimulation has been suggested as an alternative, particularly in failed unilateral lead placements, for potential salvage or added benefit as the bladder receives bilateral innervation ([van Kerrebroeck et al, 2005](#)). The initial consideration of bilateral stimulation was based on animal studies demonstrating that bilateral stimulation yielded a more profound effect on bladder inhibition than did unilateral stimulation ([Schultz-Lampel et al, 1998a, 1998b](#)). An animal model of unilateral versus bilateral stimulation has suggested that bilateral stimulation may be more effective overall (based on reduction of detrusor overactive contractions) than unilateral stimulation ([Kaufmann et al, 2008](#)).

There has been only one prospective clinical study to demonstrate the differences in unilateral versus bilateral stimulation ([Scheepens et al, 2002](#)). This study was a prospective randomized

crossover design in which all patients underwent unilateral as well as bilateral test stimulations to assess the benefits of bilateral stimulation. Both unilateral and bilateral test stimulation was continued for 72 hours, and the patients were randomly assigned to start with unilateral or bilateral stimulation. No significant difference was found in the unilateral versus bilateral group with regard to urgency urinary incontinence, frequency, or severity of leakage in the OAB group, although overall results were impressive in both categories. The retention group had better parameters of emptying (volume per void) in bilateral compared with unilateral stimulation. Still, the numbers were too small in the retention group for adequate conclusions to be made. **It appears that the data as presented, at least from a clinical perspective, do not suggest a large role for routine bilateral stimulation for most patients.** Perhaps there will be subgroups that may benefit more than others (e.g., retention patients), but larger scale studies with good methodology as shown in the study by [Scheepens and colleagues \(2002\)](#) will be required. Still, if the overall success rates of patients undergoing sacral neuromodulation could be increased, more patients could ultimately be helped. Accordingly, [Pham and colleagues \(2008\)](#) examined 124 patients undergoing stage I sacral neuromodulation and stratified patients into unilateral and bilateral groups, retrospectively. Successful stage I trials were noted in 58% of unilateral patients and 76% of bilateral patients. An important component that still needs to be evaluated is whether it is cost-effective to “routinely” place bilateral leads in the setting of most unilateral lead success rates approaching 70% and 80%. Perhaps the challenge lies in the fact that many consider sacral neuromodulation near end of the line therapy and accordingly try to optimize results with bilateral leads.

Selective Nerve Stimulation

Pudendal Nerve

Because the bladder afferent reflex works through sacral interneurons that then activate storage through pudendal nerve efferent pathways directed toward the urethral sphincter, the pudendal nerve is a logical target for developing neuromodulation therapies. The earliest attempts to manipulate this reflex through electrical stimulation were based on direct pelvic floor muscle stimulation by Caldwell and associates ([Caldwell, 1963](#); [Caldwell et al, 1965](#)) and others with the development of the first implantable and external pelvic floor stimulators, anal plug stimulator ([Hopkinson and Lightwood, 1966, 1967](#)), and intravaginal pessary stimulation ([Alexander and Rowan, 1968](#); [Erlandson et al, 1977](#); [Fall et al, 1977](#); [Fall, 1985](#)). To deliver optimal stimulation to the nerve directly, selective pudendal nerve stimulation was introduced by [Vodusek and coworkers \(1986\)](#) and shown to have an inhibitory effect on the micturition reflex.

Neurophysiologic studies reveal that SNS works for bladder storage disorders by a similar inhibition of the micturition reflex as a result of electrical stimulation of sensory afferent fibers, in particular by depolarization of A α and A γ somatomotor fibers that affect the pelvic floor and external sphincter and thus inhibit detrusor activity ([Hohenfellner et al, 1992](#)). Because many of the sensory afferent nerve fibers contained in the sacral spinal nerves originate in the pudendal nerve, the pudendal nerve afferents are important targets for neuromodulating the inhibitory reflex on the micturition reflex ([Peng et al, 2008](#); [Woock et al, 2008](#); [Yoo et al, 2008](#)). Furthermore, high-frequency electrical stimulation of this nerve may achieve blockade of external sphincter contractions leading to sphincter relaxation ([Gaunt and Prochazka, 2009](#)). Direct pudendal nerve neuromodulation stimulates more pudendal afferents than SNS provides and may do so without the side effects of off-target stimulation of leg and buttock muscles. Thus techniques for direct pudendal nerve stimulation at alternative locations to the sacral foramen are being developed. [Spinelli and associates \(2005\)](#) modified existing sacral neuromodulation technology and adapted it to pudendal nerve stimulation and realized the need for more sensitive neurophysiologic guidance to better guide stimulation to the pudendal nerve target. Trials using different techniques and devices

are underway for selective pudendal nerve stimulation within the ischial rectal fossa and the pure sensory afferent branch of the pudendal nerve at the level of the symphysis bone referred to as the dorsal genital nerve.

The Bion device (Boston Scientific, Natick, MA) is a minimally invasive implantable mini-stimulator with an integrated electrode for nerve neuromodulation. Early feasibility trial results of the Bion device placed at the level of the pudendal nerve exiting the Alcock canal indicate that a considerable reduction in the degree of DO incontinence can be obtained in refractory cases, including those cases of failed SNS neuromodulation ([Bosch, 2005](#)). Clinical trials of the rechargeable Bion device were halted in the United States and Europe.

External Periurethral Nerve

A relatively new way to stimulate the bladder has been investigated and is now underway with clinical trials in the use of external periurethral neuromodulation ([Nissenkorn et al, 2004, 2005](#)). This device basically entailed placement of a lead and generator apparatus in the periurethral location while the generator was in the lower abdomen subcutaneous space. The lead then stimulated the sphincter apparatus and nerves associated with this structure, presumably. Whereas their early results are fairly impressive, the device may help both urgency and stress urinary incontinence (16 patients with stress urinary incontinence were treated; 9 were dry during electrostimulation, and the remainder had a 74% reduction in pad weights). The exact positioning of the electrodes seems to be in the area proximate to the external urethral sphincter, thereby allowing for direct access to afferent nerve fibers ([Whiteside et al, 2009](#)). How this therapy benefits patients will be interesting because it has many potential uses, including stress and urgency urinary incontinence, pain syndromes, and neuromuscular disorders of the pelvic outlet.

Dorsal Genital Nerve

The dorsal genital nerves (dorsal nerve of the penis in males, clitoral nerve in females) are the terminal and most superficial branches of the pudendal nerve found at the level of the symphysis pubis. The nerves are afferent nerves that carry sensory information from the glans of the penis or clitoris. Proximally, the dorsal genital nerves form a component of the pudendal nerve and then the sacral spinal roots. As a pure sensory afferent nerve branch of the pudendal nerve, the dorsal genital nerve contributes to the pudendal-pelvic nerve reflex that has been proposed as a mechanism of bladder inhibition. Whereas squeezing the glans penis or manipulation of the clitoris is clinically known to help suppress bladder contractions as observed in behaviors of voiding avoidance, direct electrical stimulation of these organs does not produce a significant effect on the micturition reflex as measured by urodynamics during the storage phase ([Yalla et al, 1978](#); [Kondo et al, 1982](#)). However, direct dorsal genital nerve electrical stimulation in experimental and clinical studies appears promising in producing an inhibition of the micturition reflex.

Results in laboratory animals and in persons with SCI have demonstrated that electrical stimulation of the dorsal genital nerves inhibits bladder contractions ([Craggs and McFarlane, 1999](#)). In anesthetized cats ([Sundin et al, 1974](#); [Jiang and Lindstrom, 1999](#)) and in unanesthetized chronic spinal cord-injured cats, reflex bladder contractions could be inhibited by stimulation of the genital nerves ([Walter et al, 1993](#)). Conditioning stimulation of afferents in the dorsal clitoral nerves also has been shown to suppress reflex bladder contractions in anesthetized cats ([Jiang and Lindstrom, 1999](#)). Similarly, recent work in anesthetized cats has shown that low-amplitude electrical stimulation of the S1 dorsal root (which in the cat carries the dorsal genital afferents) inhibits or abolishes ongoing reflex bladder contractions ([Jezernik et al, 2001](#)), resulting in significantly shorter bladder contractions. The micturition reflex can be activated and inhibited by stimulation of these dorsal penile afferent fibers in animal models ([Woock et al, 2008](#)).

Stimulation of the dorsal penile nerve has been tested in humans to control incontinence in individuals with SCI, increase bladder volume, and reduce bladder overactivity (Wheeler et al, 1992, 1994). Penile nerve stimulation was painless, with no side effects, was effective for inhibiting DO, and may be adaptable for chronic home use as an alternative to current therapy (Wheeler et al, 1992). Similar experiments have shown that stimulation of the dorsal nerve of the penis abolishes reflexive bladder contractions and increases bladder capacity in persons with SCI (Lee and Creasey, 2002). These results demonstrate that electrical stimulation of the dorsal genital nerves can abolish DO and increase bladder capacity in individuals with neurogenic DO as a result of spinal injury. Feasibility trials with this approach have been completed and demonstrate in a small series that 81% of patients experienced a 50% or greater improvement in urgency and 47% reported a 50% or greater reduction in incontinence episodes (Goldman et al, 2008). This approach seems to have further advantages in being minimally invasive, office based, and without the need for fluoroscopy or prone positioning.

Posterior Tibial Nerve

The posterior tibial nerve is a mixed sensory and motor nerve containing fibers originating from spinal roots L4 through S3 that modulate the somatic and autonomic nerves to the pelvic floor muscles, bladder, and urinary sphincter. On the basis of translational findings of the traditional Chinese practice of using acupuncture points over the common peroneal or posterior tibial nerve to inhibit bladder activity, McGuire and associates (1983) used transcutaneous stimulation of the common peroneal or posterior tibial nerve for inhibition of DO. PTNS (Urgent PC, CystoMedix, Anoka, MN) as approved by the FDA currently consists of weekly 30-minute stimulation treatments provided by insertion of a small-gauge stimulating needle approximately 5 cm cephalad from the medial malleolus and just posterior to the margin of the tibia with the grounding electrode pad placed on the medial surface of the calcaneus (Govier et al, 2001; Cooperberg and Stoller, 2005). Increasing interest in this therapy in the United States has led to more data and similar to sacral neuromodulation experience in other conditions than OAB.

Clinical trials of PTNS have been performed in detrusor overactive conditions with and without pelvic pain (Klingler et al, 2000; van Balken et al, 2003; Vandoninck et al, 2003; Congregado Ruiz et al, 2004; Zhao et al, 2008) and urinary retention (van Balken et al, 2001; Vandoninck et al, 2003). Although clinical trials have produced variable results, PTNS is minimally invasive, demonstrates efficacy, and is easily applicable and well tolerated in all the LUT conditions studied. Peters and associates (2009b) performed a randomized trial of PTNS with tolterodine 4 mg extended release. This trial demonstrated improved global response assessments of OAB symptoms in 79.5% of PTNS patients versus 54.8% of tolterodine patients. Objective reduction in frequency, urge severity, and incontinence episodes was similar in both groups. Concern is raised about the placebo benefit of PTNS therapy and accordingly was investigated by Finazzi-Agrò and colleagues (2009) in a double-blind placebo-controlled study and 71% of patients in the PTNS group had greater than 50% improvement in OAB DO incontinence symptoms versus 0% in the placebo group. Recent outcomes have been shown in an MS subpopulation and improvements during PTNS have been demonstrated, including increases in mean first involuntary detrusor contractions and mean cystometric capacity during urodynamics (Kabay et al, 2008) and clinically long term in patients with MS (Zecca et al, 2014). One major limitation of PTNS is that there does appear to be the need for chronic treatment that may be better derived from an implantable subcutaneous stimulation device (van Balken et al, 2003) and even continuous stimulation (Oliver et al, 2003). MacDiarmid and colleagues (2010) studied the long-term effects on patients getting PTNS and global response assessments showed sustained improvements at 6 and 12 months in 94% and 96% of patients, respectively. A novel sham has been developed, and widespread study of PTNS with use of a sham

control has further validated outcomes in PTNS (Peters et al, 2009a). Still, one of the major limitations of this therapy is the need for continued and repeated sessions. This can be time-consuming yet cost comparisons (Martinson et al, 2013) suggest PTNS may be cost-effective compared with other therapies.

Transcutaneous Electrical Stimulation

Other methods of electrical stimulation have been used that seem to occupy a place midway between anal, vaginal, or perineal stimulation and sacral root stimulation. TENS devices have been used to limited degrees to achieve better tolerability to bladder filling and may have some efficacy in postponing voiding. Fall and associates (1980) described TENS use suprapubically in patients with interstitial cystitis, and subsequent studies have been done to gain wider use of this modality (Lindstrom et al, 1983; Fall and Lindstrom, 1991). The exact stimulation parameters are not agreed on because different frequencies have been used; 2 Hz may stimulate pudendal afferents, whereas 50 Hz may stimulate striated paraurethral musculature. Similarly, low-frequency TENS may have some use in abolishing detrusor contractility (Bower et al, 1998). Therefore this technology is easy to perform and apply, but it may be required for extended periods to gain treatment benefits. TENS use at S2 or S3 may make some sense, because direct stimulation transcutaneously of this area may yield better results than suprapubic stimulation. Positive results have been demonstrated on the basis of urodynamic data, with improved bladder capacity, delay in first urge to void, and reduced detrusor instability (Bower et al, 2001; Hoebeke et al, 2001). For adequate maintenance of the benefits of this therapy it must be continued for longer durations. McGuire and associates (1983) described 16 patients with involuntary bladder contractions of varying cause who were treated with common peroneal or posterior tibial nerve patch electrode stimulation: 12 patients initially were dry, 3 were improved, and 1 was "possibly improved." Ver-ecker and colleagues (1984), however, were unable to suppress hyperactivity by this method in patients with suprasacral SCI or disease. Okada and associates (1998) reported a positive experience with transcutaneous stimulation of the thigh muscle in 19 patients with DO; the maximal cystometric capacity was increased by 57% in 11 of 19 patients.

Noninvasive magnetic stimulation of the sacral roots will inhibit bladder contractions and cause effects that will persist for short times beyond the period of stimulation. This type of stimulation at present cannot be applied for prolonged periods and is currently unsuitable for long-term treatment, although it may be helpful for preliminary assessment of candidates for chronic sacral root neuromodulation. The extracorporeal magnetic stimulation provided by the "chair" has been used clinically in the past but not widely used currently for OAB, stress incontinence, and pelvic pain (Galloway et al, 2000). No other prospective data on this technology are available for OAB; furthermore, the exact mechanism of action, if effective, remains to be explained, namely, magnetic, nerve root or peripheral nerve, or intramural nerve stimulation.

Emerging Role for OnabotulinumtoxinA versus Sacral Neuromodulation in Overactive Bladder

The increasing use of OBTX in the therapy for OAB has yielded questions to how to decide whether to use OBTX or sacral neuromodulation in patients with refractory OAB. The American Urological Association Guidelines (Gormley et al, 2012) listed both therapies in the refractory setting, but clearly one must be aware of some pros and cons of each therapy to assist the patient in deciding which treatment is best for each patient subtype. Although many patients may do fine with either therapy, some scenarios may tilt the decision making in favor of one therapy over another. As mentioned, there is a large-scale randomized trial being done in the United States (200 IU OBTX vs. InterStim sacral neuromodulation) with the goal of helping answer this exact question, but until these results are available, one can only speculate as to which treatment

is better overall and which scenario portends the best outcome. At present, patients with emptying disorders or those at risk for urinary retention who do not want to catheterize would not be ideal candidates for OBTX. Furthermore, these patients need to be aware of the re-treatment intervals approximately every 6 months and this may aid in decision making. On the contrary, if someone has neurogenic conditions, is not willing to undergo an implant (permanent), or may need future MRIs, sacral neuromodulation becomes a less attractive option. The Anticholinergic vs. Botox Comparison (ABC) trial (Visco et al, 2012) sheds light on the use of 100 IU of OBTX because it may work only marginally better than higher dose anticholinergics. When more comparative data are available, the clinician will have a better understanding of the optimal place for each respective treatment.

Complications and Troubleshooting of Sacral Neuromodulation

With the widespread adoption of sacral neuromodulation, an increasing need has developed to understand the complications of this therapy and learn how to troubleshoot the devices when responses change. It appears that the introduction of the tined lead concept has changed the frequency and profile of the complications that were once only technology related while keeping the patient-related complications at the same frequency.

Published Series

The SNS study group has published several reports on the efficacy and safety of the procedure for individual indications (Siegel et al, 2000). The complications were pooled from the different studies on the basis of the fact that the protocols, devices, efficacy results, and safety profiles were identical. The studies recruited 581 patients, 219 of whom underwent implantation of the InterStim system. The complications were divided into those related to percutaneous test stimulation and those that are postimplant-related problems. Of the 914 test stimulation procedures done on the 581 patients, 181 adverse events occurred in 166 of these procedures (18.2% of the 914 procedures). Most complications were related to lead migration (108 events, 11.8% of procedures). Technical problems and pain represented 2.6% and 2.1% of the adverse events, respectively. For the 219 patients who underwent implantation of the InterStim system (lead and generator), pain at the neurostimulator site was the most commonly observed adverse effect at 12 months (15.3%). Surgical revision of the implanted neurostimulator or lead system was performed in 33.3% of cases (73 of 219 patients) to resolve an adverse event. This included relocation of the neurostimulator because of pain at the subcutaneous pocket site and revision of the lead for suspected migration. Explant of the system was performed in 10.5% for lack of efficacy. One should consider the fact that, at the time, the generator was implanted in the lower abdomen. This profile of complications has changed dramatically with use of the InterStim II generator and posterior (gluteal) pocket location.

Everaert and associates (2004) reported specifically on the complications with SNS. This was a retrospective study of 53 patients who had undergone implantation of the quadripolar electrode (Medtronic InterStim, model 3886 or 3080) and subcutaneous pulse generator in the abdominal site (Medtronic Irel 2 IPG) between 1994 and 1998. Device-related pain was the most frequent problem and occurred equally in all implantation sites (sacral, flank, and abdominal). This occurred in 18 of the 53 patients (34%) and was more frequent in patients with dysuria and retention or perineal pain. Pain responded to physiotherapy in 8 patients, and no explantation was done for pain reasons. Current-related complications occurred in 11%. They performed 15 revisions in 12 patients. Revisions for prosthesis-related pain ($n = 3$) and for late failures ($n = 6$) were not successful. Similar series have been published by White and associates (2009) and show relatively low rates (30%) of adverse events and may have been predicted by trauma, body

mass index, enrollment into a pain clinic, and history of adverse events.

A review (Hijaz and Vasavada, 2005) of the tined lead approach was performed at the Cleveland Clinic from June 2002 to June 2004 when 167 patients underwent sacral neuromodulation for indications of refractory OAB, idiopathic and neurogenic urinary retention, and interstitial cystitis. In this cohort, 180 stage I operations used the tined lead approach. After 2 to 4 weeks of test stimulation, 130 (72.2%) patients proceeded to stage II implantation of the IPG.

Stage I complications can lead to explantation or revision of the tined lead. The reasons for either fall under response related, mechanical, or infection related. In this series, 50 tined leads were explanted (27.8%). The majority of lead explantations were performed for unsatisfactory or poor clinical response (46 of 50, 92%). The rest of the explantations were done for infection (4 of 50, 8%). Explantation for response reasons is not truly considered a complication as much as it is an integral part of the procedure. Stage I revisions totaled 22 of the 180 operations (12.2%). Revisions were done for marginal response (13 of 22), frayed subcutaneous extension wire (6 of 22), lead infection (3 of 22), and improper localization of stimulus (1 of 22). Eleven (50%) of the revisions proceeded to stage II generator implantation. When the revision was done for a marginal response (13 of 22), the response was ultimately clinically satisfactory in 5 of 13 (38.5%), and patients proceeded to generator implantation. Typically, when the patient reported a marginal or equivocal response during the test stimulation in the absence of infection or mechanical problems, a lead revision was offered with intraoperative sensory testing. Because 38.5% of these revisions eventually were successful and patients proceeded to stage II, this is an option to keep in mind in motivated patients with equivocal response.

As in stage I, stage II complications can be divided into explantation (generator and lead) or revision. Explantation was performed in 16 of 130 (12.3%). Explantations were done for infection and failure to maintain response in 56.3% and 43.7%, respectively. Revisions were done for infection, mechanical (generator related), and response causes. The revision rate of stage II in this series was 20% (26 of 130).

When infection at the generator site is diagnosed, the best management is explantation of the whole system. To date, no preoperative or perioperative antibiotic regimen has been decided to be best and should otherwise be left to surgeon discretion. Antibiotic consideration should otherwise be targeted toward skin site pathogens and methicillin-resistant *Staphylococcus aureus*. At least in one trial (Amend et al, 2013), interestingly, prolonged percutaneous testing did not increase infection rates in a small series of patients.

Response-related complications necessitating revision are more common (18 of 26). The algorithm for management of a patient who presents with a decreased or absent response after a successful interval is outlined in Figure 81-8.

The outlined algorithm includes testing of impedances (Fig. 81-9). Impedance describes the resistance to the flow of electrons through a circuit. Impedance or resistance is an integral part of any functioning circuit. However, if there is too much resistance, no current will flow (open). If there is too little resistance, excessive current flow results in diminished battery longevity (short). The electrical circuit that we are referring to starts at the neurostimulator's circuitry and goes through the connectors to the extension wires, through the extension connector to the lead wires, through the lead's electrodes to the patient's tissue, and back either through another electrode and up the same path to the circuitry (bipolar) or to the neurostimulator case and into the circuitry (unipolar).

If the circuit is broken somehow, electrons cannot flow. This is called an open circuit, and impedance measurements are high. Open circuits can be caused by a fractured lead or extension wires and loose connections. Patients generally feel no stimulation if an open circuit is present. In measurement of impedances by the programmer, unipolar measurements are most useful for identifying open circuits because they take one lead wire measurement at a

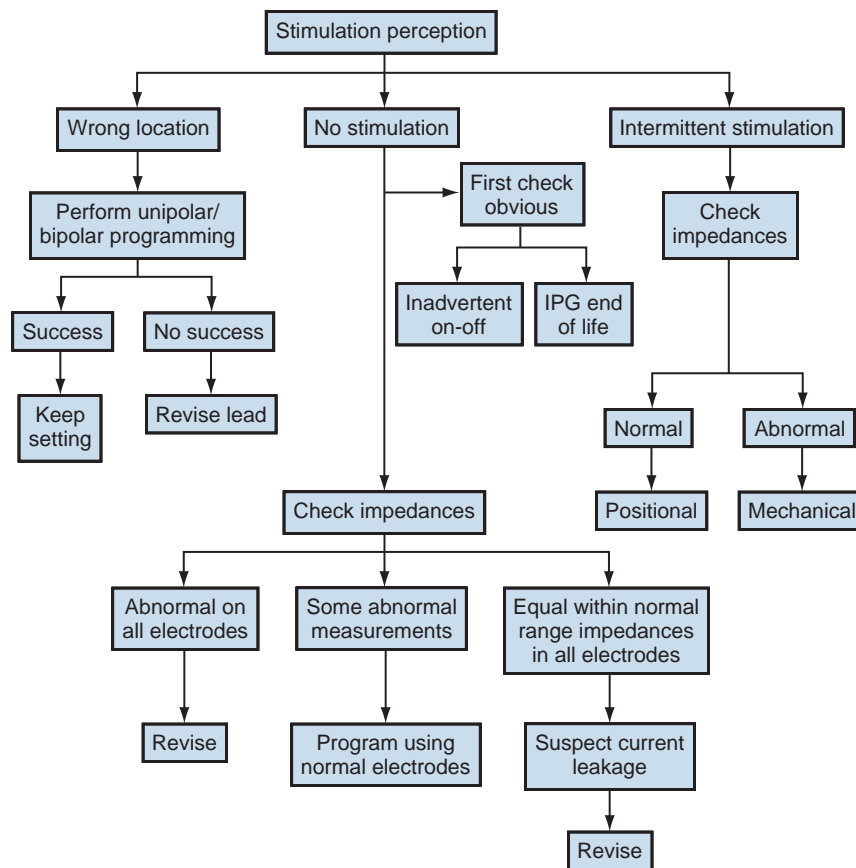

Figure 81-8. Diagnostic algorithm and troubleshooting for recurrent symptoms. IPG, implantable pulse generator.

time, immediately identifying which connection or wire has the problem.

Short circuits, which are reflected in **low impedance measurements**, can be caused by body fluid intrusion into the connectors or crushed wires that are touching each other. The electrons always will follow the path of least resistance. Patients may or may not feel stimulation, or stimulation may not be present in the correct area (i.e., the generator site) or may vary in strength (i.e., a surging sensation). In measurement of impedances by the programmer, **bipolar measurements are most useful for identifying shorts between two wires**.

Therefore impedance measurement is used as a troubleshooting tool to check the integrity of the system when a patient presents with a sudden or gradual disappearance of stimulation. Many measurements fall within the 400- to 1500-ohm range. High levels (>4000 ohms) identify open circuits, and low levels (<50 ohms) identify short circuits. Medtronic (manufacturer of the InterStim) recommends performing the impedance measurements at the time of closure of the incision; at the first programming session, to get a baseline measurement; and at any time a problem is suspected. These measurements will identify which electrodes, if any, are intact and allow the programmer to proceed with programming of only those with acceptable impedance measurements. If all electrode measurements read above 4000 ohms, a revision may be necessary.

The intraoperative algorithm for management of impedance problems includes initial testing of impedances (see Fig. 81-9). First, the tined lead is disconnected from the extension to the IPG and then dried. The connection may be irrigated with sterile water, and then the connection is dried with the 3-Fr suction device before it is reconnected again. At this stage the impedances are repeated. If they normalize, the revision can be concluded at this stage. If impedances continue to be abnormal, the 10-cm extension can be

evaluated or changed and impedances retested. If they continue to be abnormal, the lead is revised. It has been our experience that the connections to the IPG and the IPG itself seldom have anything to do with abnormal impedance values. Thus, at present, most physicians bypass much intraoperative electrodiagnostics and just change the lead to avoid any continued problems postoperatively.

Troubleshooting Algorithm

After successful completion of stage II, a number of events can occur, and the treating physician should develop an algorithm to handle these events in a timely and efficient manner. These events with their probable causes and the troubleshooting algorithm are covered in this section.

Pocket (Implantable Pulse Generator Site) Discomfort. The probable cause of pocket discomfort is pocket related or output related. Pocket-related causes of discomfort include infection, pocket location (waistline), pocket dimension (too tight, too loose), seroma, and erosion. Output-related causes include sensitivity to unipolar stimulation if this mode is used or current leak. To troubleshoot this problem the evaluating specialist is advised to do the following (Fig. 81-10):

1. Turn off the device and ask the patient if the discomfort is still present to differentiate pocket-related from output-related causes.
2. If the discomfort persists, the cause is not related to the device output. In the absence of clinical signs of infection, pocket-related causes such as pocket size, seroma, and erosion must be considered.
3. If the discomfort disappears, device output is probably causing discomfort. If the stimulation program is unipolar, switch to bipolar and see whether that eliminates discomfort. Some patients are sensitive to the unipolar mode of stimulation,

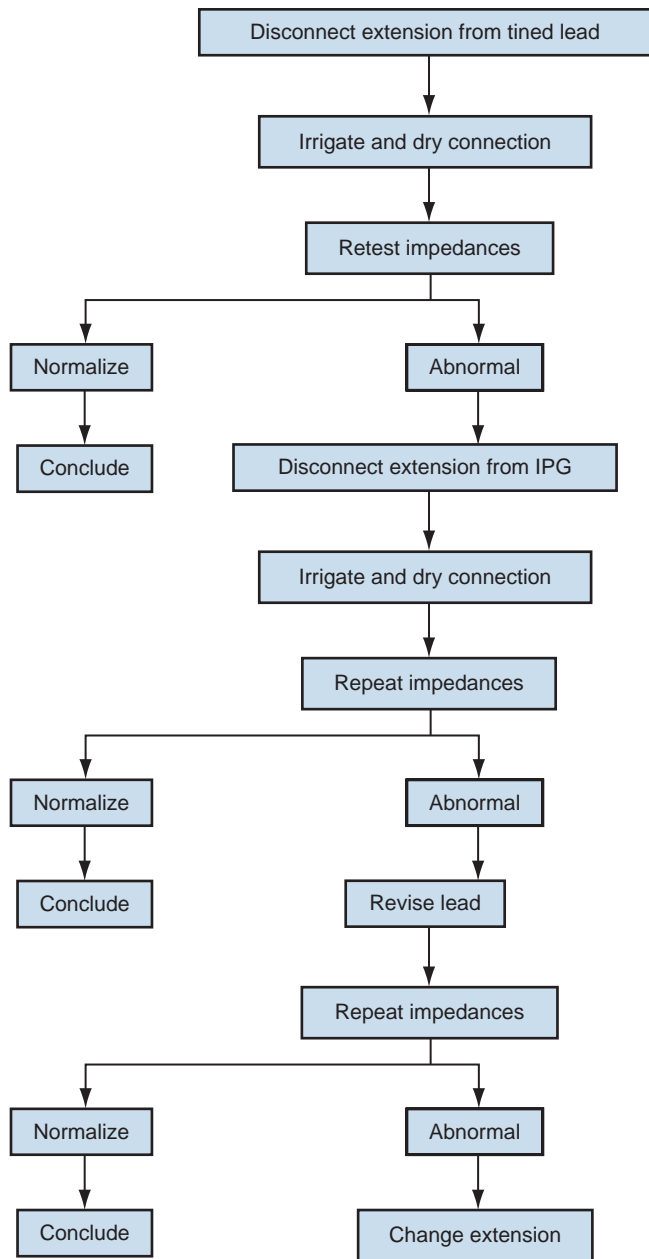

Figure 81-9. Intraoperative algorithm for impedance problem management. IPG, implantable pulse generator.

because the positive pole is the neurostimulator. Another possibility is leakage of fluid into the connector. This somehow creates a short circuit whereby the current from the device follows this fluid pathway out to the patient's tissue. Most patients report this as a burning sensation. Even though current is following this fluid out to the patient's tissue, some of the current also may be getting to the electrodes as well, so some patients feel both burning in the pocket and stimulation in the perineum. Reprogramming around this can be tried by using different electrode combinations. If reprogramming is unsuccessful, the patient is asked if the "burning" sensation is tolerable (it will not harm the patient's tissues); if it is not tolerable, a revision may be necessary to dry out the connection sites.

Recurrent Symptoms. When the patient presents with recurrent symptoms, evaluation of the stimulation perception is necessary. The possibilities are that the patient perceives the stimulation in a wrong location compared with baseline, has no stimulation, or has intermittent stimulation. Again, documentation of the exact location, amplitudes, and so on, of the best stimulation parameters

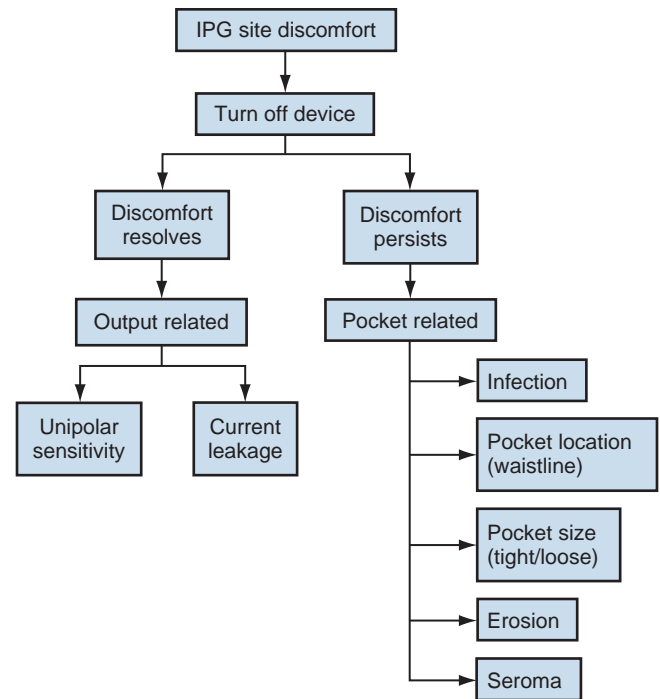

Figure 81-10. Troubleshooting algorithm for implantable pulse generator site discomfort. IPG, implantable pulse generator.

should be done early after successful implantation, to set as a baseline so when changes occur, the baseline can be noted.

Wrong Location. If the patient reports that the stimulation location or pattern has changed, it is best to go back to each unipolar setting and map where the patient feels the stimulation. The device is set to 0–, case+ and the patient is asked where she or he feels the sensation; next it is set to 1–, case+ and the patient again is asked about the sensation; next it is set to 2–, case+ and finally to 3–, case+. If these combinations do not confirm the target area, the next step is to start programming bipolar combinations. When those are exhausted, sometimes increasing the pulse width widens the stimulation area. If the programming possibilities are exhausted, revision for lead repositioning or relocation to the other side may be necessary.

No Stimulation. The obvious is checked first. The device parameters must be set high enough, an inadvertent on-off is checked (set magnet switch off to avoid inadvertent magnet activations), and whether the IPG is nearing the end of its life is checked. Next, impedance readings are performed, paying close attention to unipolar impedances. These impedances measure one lead wire with the case, so it is easy to isolate a problem. Using unipolar impedances, it is possible to tell which lead wires are still intact and which ones are not, as mentioned previously. Programming of the electrodes is then continued with acceptable impedance measurements. Bipolar measurements are checked to rule out short circuits as well (very low impedance measurements). If programming around the malfunctioning lead does not restore the stimulation, the patient will often need to undergo revision.

Intermittent Stimulation. Again, inadvertent on-off is checked. Intermittent stimulation can be caused by either a loose connection or positional sensitivity. If a loose connection is suspected, palpating the connection site and re-creating the intermittency is a good clue as to where the problem lies. Taking impedances while the patient reports the stimulation intermittently determines whether the problem is positional (acceptable impedances are still present) or mechanical (when the patient feels stimulation go off, the impedances are high). With positional sensitivity, the lead position shifts when a patient moves in a certain direction (e.g., the patient reports that the stimulation goes away on standing). The lead position may have moved farther from the nerve during standing, and

the amplitude may just need to be increased. Intermittent stimulation represents a challenging dilemma to troubleshoot.

ELECTRICAL STIMULATION FOR EMPTYING DISORDERS

There exists strong evidence to suggest that neuromodulation works through supraspinal pathways (see the section on neurophysiology of electrical stimulation). The question of how it works for refractory DO as well as for urinary retention is based on changes in supraspinal pathways and perhaps the guarding reflex. It is important to understand that before neuromodulation, neurostimulation was applied in different forms to achieve bladder emptying. Still, neurostimulation has a role today in management of disorders of bladder emptying and has evolved through many different versions before its current techniques.

Electrical Stimulation Directly to the Bladder or Spinal Cord

Clinical trials of direct electrical stimulation of the bladder to facilitate emptying originated in 1940 but have met with only partial success and intermittent enthusiasm since then (Wein and Barrett, 1988). Direct electrical stimulation was most effective in patients with hypotonic and areflexic bladders. Initial success, defined as low PVR urine volume with sterile urine, was achieved in only 50% to 60% of patients, and secondary failure often supervened, usually related to fibrosis, electrode malfunction, bladder erosion, or other equipment malfunction. The spread of current to other pelvic structures with a stimulus threshold lower than that of the bladder often resulted in abdominal, pelvic, and perineal pain; a desire to defecate or defecation; contraction of the pelvic and leg muscles; and erection and ejaculation in male patients. It was also noted that the increase in intravesical pressure was generally not coordinated with bladder neck

opening or with pelvic floor relaxation and that other measures to accomplish these ends could be necessary. Direct electrical stimulation of the sacral spinal cord was also performed as an attempt to take advantage of the remaining motor pathways to initiate micturition. Although some short-term success was noted, many of the side effects seen with direct bladder stimulation occurred as well because the stimulus applied in this way was also unphysiologic. Enthusiasm for both of these approaches has waned considerably, and resurrection seems unlikely.

Electrical Stimulation to the Nerve Roots

For the past 25 to 30 years, Brindley (1993) and the Tanagho group (Tanagho and Schmidt, 1988; Tanagho et al, 1989) pursued neurostimulation for the treatment of voiding dysfunction. The use of electrical stimulation for storage disorders and pelvic floor dysfunction has been covered. The focus of this section is on the use of anterior root electrical stimulation to facilitate emptying.

The Brindley device is the one most commonly used. Prerequisites for such use are described by Madersbacher and Fischer (Fischer et al, 1993) as (1) intact neural pathways between the sacral cord nuclei of the pelvic nerve and the bladder and (2) a bladder that is capable of contracting. The chief applications are in patients with inefficient or nonreflex micturition after SCI. Simultaneous bladder and striated sphincter stimulation is obviated by sacral posterior rhizotomy, usually complete, which eliminates reflex incontinence and improves low bladder compliance, if it is present (Brindley, 1994). The stimulation sequences and parameters themselves and their neurophysiologic consequences lead to less striated sphincter dyssynergia, even without posterior rhizotomy, than is seen in reflex micturition in a patient with SCI. Complete sacral deafferentation is usually performed, however, with the exception listed by Brindley as those patients who have genital sensation or useful reflex erections. Electrodes are applied intradurally to S2, S3, and S4 nerve roots, but the pairs can be activated independently (Fig. 81-11). The detrusor is usually

Figure 81-11. Brindley-Finotech system for sacral root stimulation. A, Transmitter to deliver current. B, External antenna. C, Internal stimulator to drive current. D, Electrodes to deliver stimulation. E, Spinal nerves. F, Bowel. G, Bladder. (Courtesy NDI Medical, Cleveland, OH.)

innervated primarily by S3 and to a smaller extent by S2 or S4. Rectal stimulation is by means of all three roots equally. Erectile stimulation is chiefly by S2, with a small contribution from S3 and none from S4. Micturition, defecation, and erection programs are possible, with stimulus patterns set specifically for each patient (Brindley, 1994). The ventral sacral roots, however, carry both parasympathetic fibers to the bladder and somatic fibers to the striated sphincter. Ventral root stimulation therefore occasionally results in detrusor–striated sphincter dyssynergia.

The current Brindley stimulator uses the principle of *post-stimulus voiding*, a term first introduced by Jonas and Tanagho (1975) to obviate this. Relaxation time of the striated sphincter after a stimulus train is shorter than the relaxation time of the detrusor smooth muscle. When interrupted pulse trains are used, voiding is achieved between the pulse trains because of the sustained high intravesical pressure. This concept and other methods that are available to overcome the stimulation-induced sphincter dyssynergia and allow low-pressure emptying are nicely reviewed by Rijkhoff and colleagues (1997). Poststimulus voiding has a few shortcomings, described in this article, because voiding occurs in spurts at above-normal bladder pressures; when the stimulus parameters are not properly adjusted the detrusor pressures can become too high, putting the upper tracts at risk; and movement of the lower limbs occurs during stimulation because the nerve roots also contain fibers innervating leg musculature, and this movement can be cumbersome for the patient.

Brindley (1994) carefully reviewed the experience in the first 500 patients treated with his prosthesis with a total follow-up, at that time, of 2033.5 years. Of the total, 2 patients were lost to follow-up and 21 died. Of the deaths, two were from septicemia (one definitely unrelated to the implant and the specifics of the other unmentioned) and one from related renal failure; the causes of five were unknown. Ninety-five reoperations were required for repair, six stimulators were removed (four infected), and two were awaiting repair. In 45 patients the stimulator was believed to be intact but not used for various reasons. In all others the stimulators were in use (411 for micturition and in most for defecation and in 13 for defecation alone) and the users were believed to be “pleased.” Upper tract deterioration was reported in only 2 of 365 patients with full deafferentation and in 10 of 135 with incomplete or no deafferentation. Two of these 10 had impaired renal function, and 1 died of this condition.

van Kerrebroeck and associates (1997) reported the results of use of the Finetech-Brindley stimulator in 52 patients. These patients were selected by screening 226 patients; complete posterior sacral root rhizotomies were performed in all. Thirty-seven of the patients had 6 months of follow-up; in these patients, complete daytime continence was achieved in 73% and night-time continence in 86%. There were significant increases in bladder capacity and bladder compliance, and residual urine was reduced significantly. Complications included cerebrospinal fluid leaks, which resolved spontaneously in 23 patients; nerve damage that resolved in 1 patient; and one implant failure caused by a cable fracture, which was successfully repaired. Sauerwein and colleagues (1999) reported in abstract form the results of sacral deafferentation and implantation of an anterior sacral root stimulator in 294 patients with SCI. Bladder spasticity was relieved in all. In 50%, micturition was achieved by stimulating S4 and S5 sacral ventral roots; in the remaining cases, it was achieved by stimulating the S2 and S3 roots. Variations in surgical approaches designed to achieve stimulation of only bladder contraction are described by Dahms and associates (2000), who also summarize overall success rates for sacral ventral root stimulation in patients with spinal cord injury at approximately 75%. Recent laparoscopic access techniques have minimized the invasiveness of this procedure and may have a role in the future in this select group of patients (Possover, 2009).

Extradural stimulation has been used by the Tanagho group (Tanagho and Schmidt, 1988; Schmidt, 1989; Tanagho et al, 1989) in the treatment of 19 patients with serious and refractory neurogenic voiding disorders. Extensive dorsal rhizotomy was performed, and a stimulator was implanted on the ventral component

of S3 or S4 with selective peripheral neurotomy (Tanagho et al, 1989). In eight patients (42%), complete success was achieved with reservoir function, continence, and low-pressure/low residual voiding with electrical stimulation. Ten patients qualified as achieving partial success, regaining reservoir function, and obtaining continence.

Electrical stimulation of the ventral sacral roots with some techniques to reduce detrusor hyperactivity and obviate striated sphincter dyssynergia has become an accepted treatment modality for LUTD in patients with SCI. Although more detailed follow-up is necessary, and further evolution will doubtless occur, these techniques have achieved remarkable improvements and success rates, which now seem to have stabilized at a high level.

Transurethral Electrical Bladder Stimulation

Intravesical electrotherapy is an old technique that has been resurrected with some interesting and promising results. The use of this technique to increase bladder capacity and compliance has been previously discussed. This section deals with the use of TEBS to facilitate bladder emptying by establishing conscious control of the initiation and completion of a micturition reflex. Fischer and colleagues (1993) describe their concept of the basis for this use as follows. In patients with incomplete central or peripheral nerve lesions—and only these patients are suitable for this method—at least some nerve pathways between the bladder and the cerebral centers are preserved but are too weak to be efficient under normal circumstances. TEBS in this situation is hypothesized to activate specific mechanoreceptors in the bladder wall. With depolarization of these receptors, activation of the intramural motor system is said to occur, resulting in small local muscle contractions that further depolarize the receptor cells. As soon as this local motor reaction reaches a certain strength, “vegetative afferentation” begins, meaning that stimuli travel along afferent pathways to the corresponding cerebral structures with the occurrence of sensation. This, in time, reinforces efferent pathways, and their stimuli create centrally induced and more coordinated and stronger detrusor contractions. Ebner and coworkers (1992) simply conceptualize the mechanism as involving an artificial activation of the normal micturition reflex and further suggest that repeated activation of this pathway may “upgrade” its performance during voluntary micturition.

Children with congenital neurogenic bladder dysfunction who have never experienced the urge to void require a biofeedback system to realize the nature and meaning of this new sensation induced by TEBS. This exteroceptive stimulation is also important for other groups of patients because it signals detrusor contractions and whether, and to what degree, voluntary detrusor control is or has become possible and, by demonstrating progress, serves as positive feedback.

This technique involves direct intraluminal monopolar electrical stimulation with a special catheter equipped with a stimulation electrode. Saline solution is used as the current-leading fluid medium in the bladder. Exteroceptive reinforcement is achieved by visual recording of detrusor contractions on a water manometer connected to the stimulation catheter. An intensive bladder training program has to be combined with TEBS and must be highly individualized. Only patients with an incomplete spinal cord lesion and with receptors still capable of reactivity and with a detrusor still capable of contractility will benefit from this technique. The achievement of conscious control requires, in addition, an intact cortex.

Fischer and colleagues (1993) used this technique in patients with incomplete SCI and other incomplete central or peripheral lesions of bladder innervation, in pediatric patients with congenital neurogenic LUTD, and in patients, especially children, with non-neurogenic dysfunctional voiding. Only patients with preserved pain sensation in sacral dermatomes S2 through S4 improved with this technique. The technique is time-consuming because stimulation must be performed on a daily basis for weeks and months, with

an individual treatment time of approximately 90 minutes. [Kaplan and Richards \(1988\)](#) reported on such therapy in myelodysplastic children, performing the treatment for 60 minutes (during a 90-minute catheterization), 3 to 5 days per week for 15 to 30 daily sessions. Of 62 patients evaluated, 42 completed at least one series of treatment. "Success" was defined differently for infants than for older children. For infants, success implied a decrease in filling pressure, an increase in the quality of bladder contraction, and a decrease in residual urine. For older children, this type of result implied a heightened awareness of detrusor contractions before and during a contraction, maintenance of low-pressure filling, effectively emptying detrusor contractions with low residual urine, and either a conscious urinary control or timely enough sensory input to allow clean intermittent catheterization for continence. Of children who initially had some detrusor contraction on initial evaluation, 80% were said to have achieved some or all of the success parameters. Of those with no initial detrusor activity, 33% achieved some success.

Other reports have been less optimistic. [Lyne and Bellinger \(1993\)](#) reported the results of TEBS treatment of 17 patients with neurologic dysfunction, 10 with myelomeningocele, and 2 with lipomeningocele. Ultimately, all patients showed detrusor contraction during therapy (12 did so initially), but results related to increased bladder capacity and improved continence were disappointing. Five patients showed minor positive changes in continence. After completion of therapy in 12 patients who had serial cystometry, 5 experienced an increase in capacity (14% to 158%) and 4 a decrease (7% to 37%). [Decter and associates \(1994\)](#) used TEBS in 25 patients with neurogenic voiding dysfunction. TEBS was correlated with an increase from 18 to 24 in the number of patients who manifested contraction on stimulation and from 3 to 12 in the number who sensed contraction during stimulation. However, cystometry showed a more than 20% increase in the age-adjusted bladder capacity in only 6 of 18 patients with serial studies and clinically significant improvements in end-filling pressures in 5 of these. A telephone questionnaire revealed that 10 of 18 patients or parents perceived an improvement in bladder function, but the authors stated that "the limited urodynamic benefits our patients achieved have not materially altered the daily voiding regimen and, because of these factors, we are not enrolling any new patients in our . . . program." This technique is certainly controversial. Some question the theoretical basis and the definitions of "success" applied to patients treated. Currently, even [Kaplan \(2000\)](#) does not seem enthusiastic about the use of this technique to attain the goal of volitional voiding, and [Decter \(2000\)](#), as previously pointed out, stated that, in his opinion, TEBS is a modality with limited clinical efficacy for facilitation of filling-storage and emptying.

Sacral Neuromodulation of Emptying Disorders

Sacral neuromodulation has been successful in patients with idiopathic nonobstructive retention, in patients with retention secondary to deafferentation of the bladder after hysterectomy, and in patients with Fowler syndrome ([Dasgupta et al, 2004; De Ridder et al, 2007](#)). Patient factors predictive of success have been sought, and increasing numbers of reports are differentiating results of sacral neurostimulation in urinary retention based on the functional disorders causing the condition, detrusor acontractility, and functional outlet obstruction. [Bross and coworkers \(2003\)](#) evaluated the predictive ability of the carbachol test and concomitant diseases in patients with an acontractile bladder. Whereas 33% of patients had a successful bilateral percutaneous nerve evaluation, a positive carbachol test result was not predictive of success. [Goh and Diokno \(2007\)](#) in a retrospective study of patients implanted for nonobstructive urinary retention found a statistically significant difference in predicting success of test stimulation for patients with a preimplantation ability to void (>50 mL) versus nonvoiders. Further evidence of the predictive role of detrusor function was reported by [Bertapelle and colleagues \(2008\)](#) in developing a detrusor contractility test using urodynamics in conjunction with sacral neurostimulation in urinary retention as exclusion criteria for sacral

neurostimulation; this test appears to be a reliable tool to rule out detrusor acontractility resulting from irreversible bladder myopathy or complete neurogenic lesion and to predict success of permanent sacral neuromodulation.

A large, prospective, randomized multicenter trial to evaluate the efficacy of SNS for urinary retention was performed by [Jonas and colleagues \(2001\)](#). After a percutaneous nerve evaluation period of 3 to 7 days, 68 patients (38% of those evaluated) with chronic urinary retention qualified for permanent implantation. Patients were randomly assigned to the treatment or control group, in which treatment was delayed for 6 months. Successful results were initially achieved in 83% of patients who received the implant, with 69% able to discontinue intermittent catheterization completely. At 18 months, 71% of patients available for follow-up had sustained improvement. These results have been corroborated by others with longer follow-up ([Datta et al, 2008; White et al, 2008](#)).

[Aboseif and coworkers \(2002\)](#) evaluated the efficacy and change in quality of life in patients with idiopathic, chronic, nonobstructive functional urinary retention. Thirty-two patients with idiopathic retention requiring intermittent catheterization underwent percutaneous nerve evaluation. Permanent implants were placed in 20 patients (17 women) who showed more than 50% improvement in symptoms. Eighteen patients were subsequently able to void and no longer required intermittent catheterization; one patient required bilateral SNS implants. Average voided volumes increased from 48 to 198 mL, and PVR volume decreased from 315 to 60 mL. Eighteen patients reported more than 50% improvement in quality of life, although the questionnaire used in the study was not described. Significant score improvements in the Beck Depression Inventory and SF-36 after sacral root neuromodulation for retention have been demonstrated by [Shaker and Hassouna \(1998\)](#). Overall success rates of the percutaneous nerve evaluation range from 33.3% to 100% ([Koldewijn et al, 1994; Scheepens et al, 2002; Spinelli et al, 2003](#)). Improvement in patients with retention may not be as rapid as in patients undergoing sacral root stimulation for other reasons. A percutaneous nerve evaluation period of at least 2 to 3 weeks and a permanent implant lead evaluation of 4 weeks or more have generally been recommended. Furthermore, bilateral or caudal SNS for urinary retention may be considered initially or for unilateral SNS trial failures, although this technique is performed infrequently and is less studied to date ([van Kerrebroeck et al, 2005; Maher et al, 2007; Pham et al, 2008](#)).

Percutaneous Tibial Nerve Stimulation for Emptying Disorders

PTNS also has been studied in the setting of nonobstructive urinary retention. At present, no randomized trials exist in this scenario; however, several case series have suggested some improvement in emptying ranging from 41% to 100% ([Vandoninck et al, 2003, 2004](#)). It is important to consider the exact definition of improvement of emptying. When one study used emptying "success" as being greater than 50% reduction in catheterized volume, success was 41%; when the definition changed to greater than 25%, success increased to 67%. Still to date, no long-term data are available for this therapy in nonobstructive retention cases.

FUTURE RESEARCH AND CONCLUSIONS

During the past century, neurostimulation and neuromodulation that originated in the 19th century have been clinically adopted. Advances in electrical innovations and our understanding of neurophysiology have provided important discoveries for the care of people with neuromuscular causes of their pelvic organ dysfunctions. To date, influencing these dysfunctions at the level of the sacral roots appears to have stood the test of time and has become generalizable to physicians worldwide. At the start of our next century of using this expanding therapy, we will need to urgently focus on developing the supportive clinical research needed to drive

further innovations and acceptance of wider clinical indications and applications. Long-term surveillance studies and randomized clinical trials to compare different techniques and nerve locations and to evaluate placebo effects are critically needed, as are more studies to elucidate modes of action to improve stimulation applications, selection of patients, and therapeutic results.

The introduction of new stimulation methods as well as application of these methods to different nerve locations will continue to provide improved treatment alternatives. In addition, these innovations will provide the ability to further develop testable hypotheses of more basic questions on electrical neurostimulation, neuromodulation, and neurophysiology of the autonomic, somatic, and central pathways that regulate pelvic organ function. Such questions need to address the observed lack of neural plasticity-induced changes with long-term neuromodulation and neurostimulation despite acute cellular changes identified in nerve signaling molecules secondary to magnetic and electrical field changes.

In OAB, the emerging use of OBTX in comparison to neuromodulation will be of much interest to the clinician and pelvic health specialist. A large-scale trial is currently underway in the United States randomizing patients with urge incontinence to 200 IU of OBTX or sacral neuromodulation (InterStim). This trial will generate much needed data on both therapies and may shed more light on ideal subjects for either modality. Thus, even without the efficacy data being available, one should be mindful about the potential for retention side effects in use of OBTX therapy, as is well known. Clearly in some patients, this is favored and may then improve overall treatment success and satisfaction.

In their present form, neurostimulation and neuromodulation work acutely through continuous electrical activity without inducing long-term neuroplastic changes. Therefore future technologies are likely to provide closed-loop conditional stimulation, much in the same manner as “on-demand” cardiac pacemakers and defibrillators do, as a means to obtain better efficacy without additional adverse electric field effects. The development of change from the present open-loop stimulation to closed-loop conditional stimulation will necessitate innovations in neurosensing of pathologic neuromuscular events of the pelvis that will lead to on-demand therapeutic electrical activity. These innovations will in turn have a profound effect on our diagnostic ability to predict clinical responses to neurostimulation and neuromodulation as we seek to maximize our benefit-risk and benefit-cost ratios in patient care.

KEY POINTS

- Neuromodulation is a field clearly in its infancy.
- Current techniques of sacral neuromodulation are indicated for treatment of refractory urgency/frequency, urgency urinary incontinence, and nonobstructive urinary retention.
- Sacral neuromodulation has yielded successful stage I to stage II conversion rates based on 50% symptom improvement in more than 60% of patients for urgency/frequency and urgency urinary incontinence.
- The exact best nerves to stimulate have yet to be realized, but data seem to be focusing on more selective nerve stimulation, particularly in complex subgroups such as patients with neurogenic bladders. Focused research on risk factor analysis of who is the best candidate for therapy will be beneficial to selection criteria.
- Transurethral electrical stimulation has fallen out of favor for the most part.
- Transcutaneous electrical stimulation, although demonstrating good efficacy, seems to have a more limited role because of the constant need to administer the therapy, but its minimal invasiveness may allow a resurgence in interest in this therapy.
- Expanding indications for neuromodulation are likely to dominate the literature in the coming years as comfort with neuromodulation increases and more challenging subgroups are addressed.

Comparisons of Incontinence Procedures

Continence in women results from a complex interplay of anatomic and physiologic properties of the lower urinary tract (bladder, urethra and sphincter, and pelvic floor) acting under the coordinating control of an intact central and peripheral nervous system. The role of the pelvic floor is to provide support to both the bladder and the urethra and to facilitate normal abdominal pressure transmission to the proximal urethra, thereby maintaining continence.

Stress incontinence is a symptom, a sign, and a clinical diagnosis; the clinical symptom is that of involuntary loss of urine associated with increased intra-abdominal pressure, such as occurs during coughing and sneezing. The International Continence Society defines urodynamic stress incontinence as the involuntary loss of urine during increased intra-abdominal pressure during filling cystometry, in the absence of detrusor (bladder wall muscle) contraction (Abrams et al, 2002). Thus, urodynamic evaluation is a prerequisite for the diagnosis of urodynamic stress incontinence. Therefore, in discussing stress incontinence, this chapter refers to women with stress urinary incontinence (SUI) diagnosed on the basis of symptoms alone or urodynamically proven, so-called urodynamic stress incontinence.

Treatment options for SUI include conservative techniques and both pharmacologic and surgical interventions. In general, surgical procedures to treat SUI aim to improve the support to the urethrovaginal junction and to correct deficient urethral closure. There is a contemporary lack of consensus, however, regarding the precise mechanism by which continence is achieved in the “normal asymptomatic woman” and therefore not surprisingly in how “normality” is restored by surgical manipulation. Anti-incontinence surgery is usually used to address the failure of normal anatomic support of the bladder neck and proximal urethra, and intrinsic sphincter deficiency. Anti-incontinence surgery does not necessarily work by restoring the same mechanism of continence that was present before the onset of incontinence. Rather, it works by a compensatory approach, creating a new mechanism of continence (Jarvis, 1994a).

THERAPEUTIC OPTIONS

The surgeon’s preference, coexisting problems, and anatomic features of the patient and her general health condition influence

the choice of procedure. Numerous surgical methods have been described, but they essentially fall into seven categories (Box 82-1).

This wide variety of treatment options for stress incontinence indicates the lack of a clear consensus as to which procedure is the most effective. Several groups have reviewed the literature, often using systematic and methodical analyses of well-designed randomized controlled trials (RCTs) (Jarvis, 1994b; Black and Downs, 1996; Fantl et al, 1996; Leach et al, 1997; Moehrer et al, 2000; Lapitan et al, 2003; Moehrer et al, 2003). Most of these reviews, however, are hampered by the quality of the existing evidence base, and these reviews are based on studies of mixed quality with little standardization of the points in Box 82-2.

A review of existing literature on confounding variables affecting outcome of therapy (Smith et al, 2005) concluded the following.

1. Age may not be a contraindication to colposuspension, with success in the elderly being equivalent to success in younger patients at long-term follow-up (Gillon and Stanton, 1984; Tamussino et al, 1999), although others have reported less success with increasing age (Langer et al, 2001; Chilaka et al, 2002). Smith and associates (2009), from their review of the literature, concluded that the effect of age on outcomes is poorly defined. The effect of aging on the lower urinary tract includes a higher rate of detrusor overactivity as well as urgency incontinence and intrinsic sphincteric deficiency (ISD). In addition, older patients are more likely to have had prior interventions and may therefore have a higher rate of periurethral fibrosis and/or other abnormalities in the tissues surrounding the lower urinary tract. The presence of multiple comorbidities may also affect overall surgical outcome, including creating the possibility for increased complications and a prolonged postoperative course.
2. The influence of the level of postoperative activity has been inadequately studied, so no recommendations can be made (Smith et al, 2009).
3. There is level 4 evidence that medical comorbidity may have an impact on surgical outcomes, depending on the outcomes selected. There is level 3 evidence that psychological factors have an impact on subjective and objective outcomes in different ways (Smith et al, 2005).
4. Obesity as a confounding variable is the subject of conflicting evidence in the literature and has not been studied in a prospective fashion. Obesity has been studied only retrospectively in case series as a risk factor for success or morbidity in stress

The patients under study (with regard to age, history of prior surgery, body mass)
 The nature of the surgical technique, taking into account the surgeon's experience
 Outcome measures and follow-up

incontinence surgery (level 4 evidence). There are no prospective, randomized trials that suggest superiority of one surgical technique over another in the obese population. Some studies have suggested increased failure rates in obese patients undergoing retropubic colposuspension (Brieger and Korda, 1992; Alcalay et al, 1995). Conversely, in a retrospective study of 198 women undergoing anti-incontinence surgery, cure rates were markedly better in those undergoing Burch colposuspension (Zivkovic et al, 1999).

5. Surgery for recurrent stress incontinence has a lower success rate. One study has reported that Burch colposuspension has an 81% success rate after one previous surgical procedure has failed, but this drops to 25% after two previous repairs and to 0% after three previous operations (Petrou and Frank, 2001). Other series report excellent results for colposuspension carried out after prior failed surgery. Maher and colleagues (1999) and Cardozo and associates (1999) have shown good objective (72% and 79%) and subjective (89% and 80%) success rates with repeated colposuspension at a mean follow-up of 9 months. Nitahara and coworkers (1999) reported a 69% subjective success at a mean follow-up of 6.9 years.
6. Berglund and associates (1996) reported that the duration of symptoms is a predictor of outcome, with a better response in those with a shorter history, which as a finding was independent of type of approach (e.g., vaginal vs. retropubic). Ward and Hilton (2002), in a randomized comparison of colposuspension and tension-free vaginal tape (TVT), found no significant impact of symptom severity on outcomes for either procedure. Tamussino and coworkers (1999), in a review of 327 women assessed a minimum of 5 years postoperatively, noted that women with moderate or severe incontinence fared worse than those with milder symptoms. In their series, only Burch colposuspension was unaffected by the severity of preoperative symptoms.
7. It has been reported that as many as 23% of women undergoing urodynamics have mixed urodynamic stress incontinence and detrusor overactivity (Clarke, 1997). In a retrospective cohort study, Colombo and associates (1996b) compared 44 women with mixed incontinence with a matched group with urodynamic stress incontinence. The cure rate was 95% in the latter group compared with 75% in the former. Other studies report a less favorable outcome of 24% to 43% in those with detrusor overactivity combined with stress incontinence (Stanton et al, 1978; Milani et al, 1985; Lose et al, 1988).

Smith and colleagues (2009) concluded that surgery for urodynamic stress incontinence should not be considered contraindicated in women with mixed symptoms of SUI and

overactive bladder syndrome or mixed urodynamic findings of urodynamic stress incontinence and detrusor overactivity (grade B recommendation). All patients undergoing surgery for SUI should be appropriately counselled to have realistic expectations of outcome; this is particularly important in those with mixed symptoms or mixed urodynamic stress incontinence (grade B recommendation).

8. The International Consultation on Incontinence (ICI), although allowing the fact that there is no consensus on the definition of intrinsic sphincter deficiency, concluded that there are limited evidence-based data to support that intrinsic sphincter deficiency influences either the outcomes of surgery or the type of surgical treatment (Smith et al, 2005, 2009). It would appear that a low leak point pressure is less predictive of outcome when compared with the presence or absence of urethral hypermobility (Smith et al, 2009).

CHOICE OF SURGICAL TECHNIQUE

Two types of stress incontinence have been suggested: one associated with a hypermobile but otherwise healthy urethra, a manifestation of weakened support of the proximal urethra, and one arising from a deficiency of the urethral sphincter mechanism itself, thereby compromising the ability of the urethra to act as a watertight outlet. Hypermobility of the bladder neck and proximal urethra results from a weakening or loss of their supporting elements (ligaments, fasciae, and muscles), which in turn may be a consequence of aging, hormonal changes, childbirth, and prior surgery. It seems likely that the majority of women with SUI will also have an element of intrinsic sphincteric weakness with a variable degree of loss of the normal anatomic support of the bladder neck and proximal urethra, resulting in hypermobility. The compelling observation that one can cite for this is that a normal individual will not have leakage however much she strains.

Differentiating Relative Contributions of Hypermobility and Intrinsic Sphincter Deficiency

The influence of urethral function defined by leak point pressure or maximum urethral closure pressure (MUCP) is difficult to define because of the large variation in outcome measures used. Furthermore, other variables such as urethral mobility are often not controlled for. Intrinsic sphincteric deficiency is usually defined as a leak point pressure below 60 or MUCP below 20. A standardized test is not available to differentiate the relative contributions of intrinsic sphincter deficiency and hypermobility, and therefore few studies have been able to accurately separate their individual contributions to the development of incontinence (Chapple et al, 2005). Retropubic procedures act to restore the bladder neck and proximal urethra to a fixed, retropubic position and are used when hypermobility is thought to be an important factor in the development of that woman's stress incontinence. This may facilitate the function of a marginally compromised intrinsic urethral sphincter mechanism, but if significant intrinsic sphincter deficiency is present, it is likely that SUI will persist despite efficient surgical repositioning of the bladder neck and proximal urethra; at present this hypothesis remains unproven. In such circumstances a sling procedure (particularly a snug fascial sling) or an artificial sphincter are most likely to be the therapy of choice.

In the normal continent woman, the bladder neck and proximal urethra are supported in a retropubic position, with the bladder base being dependent. Increases in intra-abdominal pressure are transmitted to both the bladder and the proximal urethra such that the pressure difference between the two is unchanged, promoting continence (Einhorn, 1961). A valvular effect at the bladder neck created by the transmission of abdominal pressure to the dependent bladder base may also be operative here (Penson and Raz, 1996). Furthermore, with proper bladder neck support, reflex contraction

of the pelvic floor muscles during Valsalva maneuvers and coughing acts as a backboard for urethral compression (Staskin et al, 1985).

Surgical Procedures

This chapter deals with retropubic surgical procedures, usually chosen as surgical therapy for patients with stress incontinence in which there is a significant component of hypermobility.

Open retropubic colposuspension is the surgical approach of lifting the tissues near the bladder neck and proximal urethra into the area of the pelvis behind the anterior pubic bones. When it is an open procedure, the approach is through an incision over the lower abdomen. There are four variations of open retropubic col-

posuspension: Marshall-Marchetti-Krantz (MMK), Burch, vagino-obturator shelf (VOS), and paravaginal procedures.

The term *colposuspension* was originally used to denote suspension of the urethra by the vaginal wall; however, by common usage, it now generally includes the paraurethral fascia and sometimes only this without the vagina. Retropubic colposuspension urethral repositioning can be achieved by three distinctly different procedures; these are all based on a similar underlying principle, but in a spectrum in relation to the degree of the support or elevation they achieve, and their outcomes differ somewhat in the longer term.

The **Burch colposuspension** (Fig. 82-1A) is the elevation of the anterior vaginal wall and paravesical tissues toward the iliopectineal line of the pelvic sidewall with use of two to four sutures on either

Figure 82-1. A, Coronal view, diagrammatic representation of a Burch colposuspension. B, Coronal view, diagrammatic representation of a vagino-obturator shelf procedure. C, Coronal view, diagrammatic representation of a vagino-obturator shelf procedure on the left, augmented by stitching to the iliopectineal line, and a Burch procedure on the right. D, Coronal view, diagrammatic representation of a paravaginal repair. E, Diagram demonstrating the sutures in a Marshall-Marchetti-Krantz procedure and their proximity to the urethra. (From Turner-Warwick R, Chapple CR. *Functional reconstruction of the urinary tract and gynaecology: an exposition of functional principles and surgical procedures*. Oxford [UK]: Blackwell Science; 2002.)

side (Burch, 1961). The VOS repair (Fig. 82-1B) aims to anchor the vagina to the internal obturator fascia and is a modification of a combination of the Burch and paravaginal defect repair, with placement of the sutures laterally, anchored to the internal obturator fascia rather than hitching the vagina up to the iliopectineal line (Turner-Warwick, 1986), although a more recent modification does, where appropriate, insert stitches into both the internal obturator and iliopectineal line (Fig. 82-1C). The paravaginal defect repair (Fig. 82-1D) aims to close a presumed fascial weakness laterally at the site of attachment of the pelvic fascia to the internal obturator fascia (Richardson et al, 1976). The MMK procedure (Fig. 82-1E) is the suspension of the vesicourethral junction (bladder neck) toward the periosteum of the symphysis pubis (Marshall et al, 1949) and was thought to act by buttressing the paraurethral area and bringing the vesicourethral junction into a more elevated “intra-abdominal” position.

The Degree of Urethral Elevation

The extent of the urethral elevation achieved by both the Burch (see Fig. 82-1A) and the VOS suspensions (see Fig. 82-1B and C) is higher than the arcus tendineus anchorage of the paravaginal defect repair (see Fig. 82-1D).

The Configuration of the Suspensions

A particular advantage of the horizontal urethral elevation achieved by both the VOS and the paravaginal repair suspensions is the significantly lower susceptibility to tension on the urethra and to obstructive problems than with the V-shaped configuration of the Burch suspension (see Fig. 82-1A).

Tissue Approximation

Both the VOS and the paravaginal repair suspensions are anchored by tissue-approximating sutures; thus, unlike the Burch procedure, neither the VOS nor the paravaginal repair suspension is suture-dependent in the longer term once the initial healing is complete because there is direct tissue adhesion. The VOS anchorage and suspension are significantly more robust than those of the paravaginal defect repair; the elevation this procedure achieves can be further augmented by additionally including the iliopectineal ligament in the upper sutures (see Fig. 82-1C).

Laparoscopic colposuspension is the most popular of the laparoscopic incontinence procedures that were first introduced in the early 1990s (Vancaillie and Schuessler, 1991) with the premise that, as minimally invasive procedures, they would benefit patients by avoiding the major incision of conventional open surgery and shorten the time for a return to normal activity. As in open colposuspension, sutures are inserted into the paravaginal tissues on either side of the bladder neck and then attached to the iliopectineal ligaments on the same side. There are, however, technical variations in surgery with respect to the laparoscopic approach (transperitoneal into the abdominal cavity or extraperitoneal) and in the number and types of sutures, the site of anchor, and the use of mesh and staples (Jarvis et al, 1999).

ASSESSING OUTCOMES OF THERAPY

Before the best procedure is determined, several issues regarding outcome reporting need to be addressed.

Duration of Follow-Up

It is recognized that prolonged follow-up is required to assess the true benefit of an incontinence procedure. **Short-term follow-up should be considered to have begun in all studies after participants have reached 1 year of follow-up** (Abrams et al, 2005). In the short term (2 years), most procedures are successful, and success rates among procedures are similar (Leach et al, 1997). However,

with longer follow-up (>5 years), failures manifest and the true benefit of the better procedures is realized. Most studies report outcomes after short-term follow-up, and thus results must be interpreted with caution.

The Issue of Intrinsic Sphincter Deficiency

There is no consistency in the existing literature data to support the likelihood that intrinsic sphincter deficiency can influence either the outcomes or the type of surgical treatment. The main problem is that there is no uniform consensus on the meaning of *intrinsic sphincter deficiency* and how to diagnose it (Smith et al, 2005, 2009). Nevertheless it is likely in my view (unsubstantiated by any unequivocal evidence) that although mild degrees of intrinsic sphincter deficiency coexist with hypermobility in most cases, in a situation wherein intrinsic sphincter deficiency is the predominant problem, a repositioning procedure such as a colposuspension is less likely to be successful than a tight fascial sling or artificial sphincter.

The Definition of Cure

The definition of cure varies among studies. Some authors report cure of SUI only, whereas others define cure as complete continence postoperatively, implying the absence of urge incontinence as well. The assessment of cure may vary. Some authors report subjective cure based on patient history, questionnaire, bladder diary, or medical chart review; others use more objective measures, such as pad tests, stress tests, and urodynamics.

Finally, one must question whether the goal of complete continence is reasonable, given that the condition of SUI is usually a degenerative one and corrective surgery does not replace the defective components. As well, **even in normal healthy women, urinary continence is a spectrum of dryness; approximately 40% of nulliparous 30- to 49-year-olds experience some degree of incontinence with exercise** (Nygaard et al, 1990). It seems unreasonable to expect surgery for a degenerative condition to achieve results that are better than the nondegenerative state.

The Patient's versus the Physician's Perspective

A patient's satisfaction with treatment is often based on the difference between her expectations and her experiences (Sofaer and Firminger, 2005). Thus, fulfillment of positive expectations is a key element of a patient's satisfaction (Sitzia and Wood, 1997). Because expectations vary widely, satisfaction is not a standard concept. Consequently, treatment plans must be tailored to meet a nonstandard goal. An integral step in achieving this goal is the development of a patient-physician partnership that promotes the negotiation of realistic expectations.

Logically, agreement of patient and physician with respect to treatment plan and goals should improve outcomes. When a diagnosis has been made, asking patients what they already know about the condition may give clues to expectations for treatment. The “ask-tell-ask” method may be used to mend the gaps between the physician's and the patient's expectations. The physician explains the proposed treatment plan and expectations for the outcome, then encourages the patient to ask questions. The physician provides the information requested and invites questions again, continuing the process until a mutual understanding of treatments and expectations is reached (Barrier et al, 2003). This approach may prevent “surprises” such as unexpected pain of treatment, adverse events of medication, and prolonged recovery time. Elkadry and associates (2003) emphasized this point by demonstrating a significant association between feeling unprepared for surgery and the patient's dissatisfaction after pelvic reconstruction. The same investigators also reported that achievement of patient-defined goals was more predictive of a patient's satisfaction than were objective measures of surgical success.

Clearly, one or more high-quality validated symptom and quality-of-life instruments should be chosen at the outset of a

clinical trial, representing the patient's viewpoint, accurately defining baseline symptoms as well as any other areas in which treatment may be beneficial, and assessing the objective severity and subjective impact of both. Whereas I and many others think that urodynamic studies are helpful in defining the underlying pathophysiologic process in patients with incontinence, they have not been proven to have adequate sensitivity, specificity, or predictive value (Chapple et al, 2005). The ICI meeting scientific committee concluded that although urodynamic studies, such as frequency-volume charts and pad tests, are useful, there is inadequate evidence to justify pressure-flow studies for routine testing, as either entry criteria or outcome measures in clinical trials. They recommended that most large-scale clinical trials enroll subjects by carefully defined symptom-driven criteria when the treatment will be given on an empirical basis (Abrams et al, 2005).

INDICATIONS FOR RETROPUBLIC REPAIR

The treatment of SUI in women must be tailored to the individual patient. Once evaluation has identified contributing factors, a trial of conservative therapy should be pursued and surgery considered for patients who do not respond to this. Careful assessment of the patient is essential in making an accurate diagnosis (Fig. 82-2).

The selection of technique is largely based on the surgeon's preference and prior experience; bladder base and urethral hypermobility may be surgically corrected by either a vaginal or a retropubic approach. Although it has been suggested that a retropubic colposuspension should be considered in patients who frequently generate high intra-abdominal pressure (e.g., those with chronic cough from obstructive pulmonary disease and women in strenu-

ous occupations) (Appell, 1993), it could also be argued that these patients may be better served by a pubovaginal sling as well.

Specific Indications

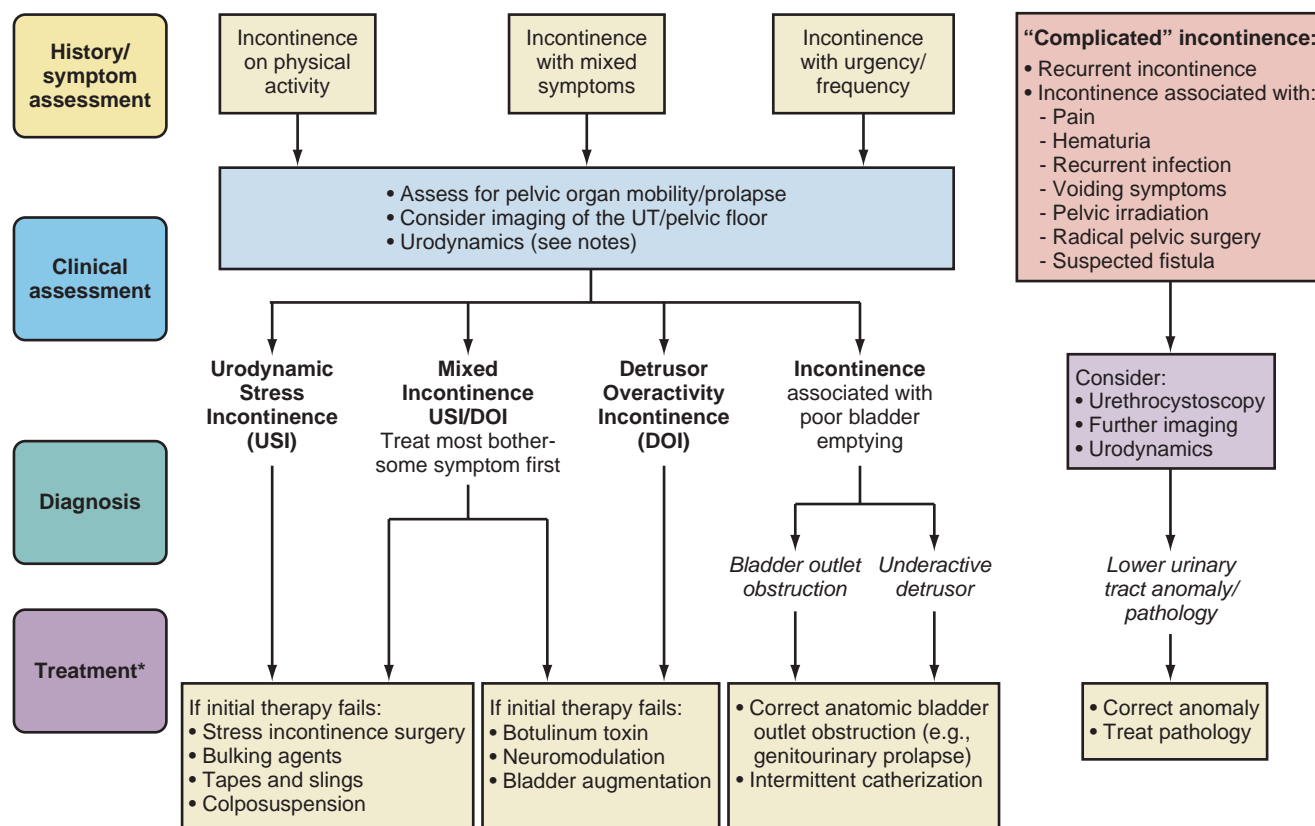

A retropubic approach for the correction of anatomic SUI is indicated (1) for a patient undergoing a laparotomy for concomitant abdominal surgery that cannot be performed vaginally and (2) where there is limited vaginal access.

Potential Contraindications

If there is a history of prior failed incontinence procedures, the existence of significant sphincteric deficiency must be suspected, even if hypermobility exists, and consideration given to performing a pubovaginal sling, although retropubic colposuspension may be successful in this scenario as well (Cardozo et al, 1999; Maher et al, 1999; Nitahara et al, 1999).

In my view, when SUI exists solely because of intrinsic sphincter deficiency (i.e., a fixed, nonfunctional proximal urethra with intrinsic urethral sphincter dysfunction), a retropubic suspension procedure is less likely to be successful because there is no hypermobility to correct and the patient is better served by a pubovaginal sling, collagen injections, or artificial sphincter (Bergman et al, 1989b). This represents a personal view that is at variance with the ICI's conclusion statement on the role of urethral occlusive forces, which states, "It would appear that a low leak point pressure is less predictive of outcome on this data when compared to the presence or absence of urethral hypermobility" (Smith et al, 2009).

In cases with a pan-pelvic floor weakness, a colposuspension should not be used in isolation but should be part of a comprehensive approach to the pelvic floor and combined as

*At any stage of the patient's care pathway, management may need to include continence products.

Figure 82-2. Algorithm for the specialized management of stress urinary incontinence in women (after the Third International Consultation on Incontinence, Monaco, 2004). UT, urinary tract.

appropriate with other alternative pelvic floor repair procedures. A retropubic colposuspension does not always adequately correct the associated vaginal prolapse that frequently coexists with bladder neck hypermobility. Although lateral defect cystocele and enterocele lend themselves to retropubic repair, a central defect cystocele, rectocele, and introital deficiency do not.

A retropubic colposuspension is contraindicated when there is an inadequate vaginal length or mobility of the vaginal tissues, for example, after prior vaginal surgery, radiotherapy, or a prior vaginal incontinence procedure (Appell, 1993). The lysis of retropubic adhesions can be performed adequately and safely by a vaginal approach in conjunction with a needle suspension procedure or pubovaginal sling.

Vaginal versus Retropubic Surgery

From a review of the literature, there is clearly a difference in the success rate of vaginal versus retropubic surgery alone with respect to correction of stress incontinence. An anterior colporrhaphy can certainly be efficacious for the correction of prolapse, with reported efficacy rates in randomized controlled studies of 42% and 57% in the management of cystoceles (Sand et al, 2001; Weber et al, 2001). For the treatment of both a cystocele and stress incontinence, an anterior colporrhaphy should be combined with a sling procedure. Goldberg and colleagues (2001), in a case-control series, demonstrated that in women with a cystocele and SUI, the addition of a pubovaginal sling to an anterior colporrhaphy significantly decreased the recurrence rate from 42% in the control group to 19% in the anterior colporrhaphy group.

Glazener and Cooper (2001) reviewed the literature on randomized or quasi-randomized trials that included anterior vaginal repair for the treatment of urinary incontinence. Nine trials were identified that included 333 women who underwent anterior vaginal repair and 599 who received comparison interventions. The researchers concluded that anterior vaginal repair was less effective than open abdominal retropubic suspension on the basis of patient-reported cure rates in eight trials, both in the medium term (failure rate within 1 to 5 years after anterior repair, 97 of 259 [37%] vs. 57 of 327 [17%], relative risk [RR] 2.29, 95% confidence interval [CI] 1.7 to 3.08) and in the long term (after 5 years, 49 of 128 [38%] vs. 31 of 145 [21%], RR 2.02, 95% CI 1.36 to 3.01). There was evidence from three of these trials that this was reflected in a need for more repeated operations for incontinence (25 of 107 [23%] versus 4 of 164 [2%], RR 8.87, 95% CI 3.28 to 23.94). These findings held irrespective of the coexistence of prolapse (pelvic relaxation), although fewer women had a prolapse after anterior repair (RR 0.24, 95% CI 0.12 to 0.47), and later prolapse operation appeared to be equally common after either a vaginal (3%) or an abdominal (4%) operation.

Long-term follow-up beyond the first year is available in only three RCTs (Bergman et al, 1989a; Liapis et al, 1996; Colombo et al, 2000). There is a low morbidity rate with anterior vaginal repair, but long-term success rates decrease with time to the extent that a 63% cure rate at 1 year fell to 37% at 5 years of follow-up (Bergman and Elia, 1995).

Based on the existing evidence, transvaginal sling procedures and open retropubic suspension procedures have similar success rates in the treatment of stress incontinence. However, with longer follow-up (and with the exception of the pubovaginal sling and loose mid-urethral tapes (see later in this chapter), patients who have retropubic procedures fare better than those undergoing vaginal repairs.

KEY POINT: RECOMMENDATION FROM THE INTERNATIONAL CONSULTATION ON INCONTINENCE COMMITTEE (SMITH ET AL, 2009)

- Anterior colporrhaphy should not be used in the management of SUI alone (grade A recommendation).

GENERAL TECHNICAL ISSUES

Retropubic Dissection

In open retropubic suspension procedures, good access to the retropubic space is crucial. This is best performed with the patient in the supine position with the legs abducted, in either a low or a modified dorsal lithotomy position with use of stirrups, allowing access to the vagina during the procedure and a perineal-abdominal progression. A urethral Foley catheter is inserted; the catheter balloon is used for subsequent identification of the urethra and bladder neck, and indeed, it is invaluable in allowing palpation of the edges of the bladder by appropriate manipulation. A Pfannenstiel or lower midline abdominal incision is made, separating the rectus muscles in the midline and sweeping the anterior peritoneal reflection off the bladder. It is essential to optimize the access to the retropubic space, and if a Pfannenstiel skin incision is made, it is advisable to use the suprapubic V modification described by Turner-Warwick and colleagues (1974). Likewise, whatever incision is made, extra valuable access to the retropubic space is obtained by extending the division of the rectus muscles down to the pubic bone and elevating the aponeurotic insertion of the rectus muscle off the upper border of the pubic bone.

The retropubic space is then developed by teasing away the retropubic fat and underlying retropubic veins from the back of the pubic bone. The bladder neck, anterior vaginal wall, and urethra are then easy to identify, often facilitated by the presence of the Foley balloon. In patients who have had previous retropubic surgery, the dissection is performed sharply, and it is important to take down all old retropubic adhesions, particularly in the face of a prior failed repair. If difficulty is encountered in the identification of the bladder neck, the bladder may be partially filled or even opened to identify its limits, and an examining finger in the vagina is invaluable in aiding the dissection (Symmonds, 1972; Gleason et al, 1976).

It is important to identify the lateral limits of the bladder as it reflects off the vaginal wall because only in this manner can one avoid inadvertent suturing of the bladder itself. Dissection over the bladder neck and urethra in the midline is to be avoided so as not to damage the intrinsic musculature. The lateral bladder wall may be "rolled off" medially and cephalad from the vaginal wall with a mounted swab and by use of countertraction with a finger in the vagina. In my experience, it is necessary to incise the endopelvic fascia. Occasional venous bleeding from the large vaginal veins is controlled by suture ligation, although it often resolves with tying of elevating sutures. To aid in the identification of the lateral margin of the bladder, it is helpful to displace the balloon of the Foley catheter into the lateral recess, where it can easily be palpated through the bladder wall.

Suture Material

Absorbable sutures were used in the original descriptions of the MMK procedure (chromic catgut), Burch procedure (chromic catgut), and VOS procedure (polyglycolic acid or polydioxanone), whereas the original paravaginal repair used nonabsorbable sutures (silicon-coated Dacron). Fibrosis during subsequent healing is likely to be the most important factor in providing continued fixation of the perivaginal fascia to the suspension sites (Tanagho, 1996); nevertheless, some surgeons believe that a nonabsorbable suture material is better because of the risk of suture dissolution before the development of adequate fibrosis (Penson and Raz, 1996). Clearly, the type of suspension suture material is a personal choice, but erosion of nonabsorbent sutures into the lumen of the bladder is a not-uncommon complication and a not-uncommon source of medical litigation (Woo et al, 1995).

Bladder Drainage

Some degree of immediate postoperative voiding difficulty can be expected after retropubic suspensions (Lose et al, 1987; Colombo et al, 1996a). Immediately postoperatively, bladder drainage may

take the form of a urethral or a suprapubic catheter, in general based on the surgeon's preference. A voiding trial is usually performed around the fifth day postoperatively. However, there is some evidence that a suprapubic catheter may be advantageous with respect to a lower incidence of asymptomatic and febrile urinary tract infection and earlier resumption of normal bladder function (Andersen et al, 1985; Bergman et al, 1987). In addition, the use of a suprapubic tube is usually more comfortable, allows the patient to participate in catheter management, and avoids the need for clean intermittent self-catheterization. Catheterization can be discontinued when efficient voiding has resumed, which is usually indicated by a postvoid residual volume either less than 100 mL or less than 30% of the functional bladder volume.

Drains

A tube drain may be placed in the retropubic space when there is concern about ongoing bleeding from perivaginal veins that may prove difficult to control with suture and electrocautery. Often, tying the suspension sutures is sufficient to stop this bleeding, but when it persists, drainage of the retropubic space is indicated. The drain is usually removed on the first to third day, when minimal output is noted.

MARSHALL-MARCHETTI-KRANTZ PROCEDURE

Technique

Marshall, Marchetti, and Krantz in 1949 described a retropubic approach for the elevation and fixation of the anterolateral aspect of the urethra to the posterior aspect of the pubic symphysis and the adjacent periosteum. Technically, the original description of the MMK procedure reported a double suture bite of the paraurethral tissue included with the vaginal wall; this may be generically entitled a cystourethropexy procedure. In 1949, Marshall and coworkers described their retropubic vesicourethral suspension in 50 patients;

38 of the patients had symptoms of SUI, and in 25 of those, prior gynecologic operations for urinary incontinence had failed. A simple suprapubic procedure was described by which the vesical outlet was suspended to the pubis (Marshall et al, 1949). In the original description, three pairs of sutures (taking double bites of tissue) were placed on each side of the urethra, incorporating full-thickness vaginal wall (excluding mucosa) and lateral urethral wall (excluding mucosa) (Marshall et al, 1949). Marchetti (1949) then modified the procedure to omit the tissue bite through the urethral wall because of concern about urethral injury. Apart from modifications in suture number and material over the years, the procedure remains the same today.

Cystourethropexy was often used as a secondary procedure for the resolution of persistent leaking after an anterior colporrhaphy. A cystourethropexy procedure does not support the posterior wall of the urethra unless the sutures include the paraurethral vaginal wall, nor does it positively reduce an anterior vaginal wall prolapse in the way that the true retropubic colposuspension procedures do. After cystourethropexy, if there is a significant urinary residual volume postcolporrhaphy with associated laxity of the anterior vagina wall, then with the descent, this applies traction to the posterior aspect of the bladder neck and tends to "tent" it open because the anterior aspect is tethered by sutures to the back of the pubis (see Fig. 82-1E). Sutures are placed on either side of the urethra (avoiding the urethral wall), taking bites through the paraurethral fascia and anterior vaginal wall (excluding mucosa). The most proximal sutures are placed at the level of the bladder neck. Each suture is then passed into an appropriate site in the cartilaginous portion of the symphysis (Fig. 82-3). However, the main technical problem relating to the MMK procedure is the difficulty of obtaining an adequately robust anchorage of the anterior wall of the urethra and the paraurethral fascia to the symphysis and the periosteum of the pubis, where the suture bites are relatively insecure. As shown in Figure 82-3, these sutures can potentially either distort the bladder neck and impair sphincter function (see Fig. 82-3A) or obstruct the bladder neck (see Fig. 82-3B). All sutures

Figure 82-3. A, Potential risk of tethering the urethra with the Marshall-Marchetti-Krantz (MMK) procedure, influencing the function of the urethral sphincter mechanism. B, Potential risk of obstruction of the urethra with the paraurethral sutures of the MMK procedure. (From Turner-Warwick R, Chapple CR. *Functional reconstruction of the urinary tract and gynaeco-urology: an exposition of functional principles and surgical procedures*. Oxford [UK]: Blackwell Science; 2002.)

are inserted, and while an assistant elevates the anterior vaginal wall, each suture is individually tied, starting with the more distal pair. The proximal, or bladder neck, suture frequently needs to be passed through the insertion of the rectus abdominis muscle. Additional sutures may or may not be placed between the anterior bladder wall and the rectus muscles to pull the bladder farther anteriorly.

Results

Krantz described a personal series of 3861 cases with a follow-up of up to 31 years and a 96% subjective cure rate (Smith et al, 2005). Short- and medium-term results with the MMK procedure have been good. Mainprize and Drutz (1988) reviewed 58 articles (predominantly retrospective) published from 1951 to 1988 for treatment outcomes in 3238 cases. The cure rate, mostly based on subjective criteria, was 88%, with an improvement rate of 91%. Jarvis's meta-analysis of studies in the literature (1994b) noted subjective continence in 88.2% (range 72% to 100%) of 2460 patients with 1- to 72-month follow-up and objective continence in 89.6% (range 71% to 100%) of 384 patients with 3- to 12-month follow-up. Whether the procedure was being done primarily or secondarily affected the outcome, with subjective continence in 92% if it was done primarily versus 84.5% if it was done secondarily. Longer-term data are limited in amount. McDuffie and colleagues (1981) reported 75% success at 15 years. More recently, Clemens and coworkers (1998) noted subjective cure or improvement (SUI and urge urinary incontinence) in only 41% of patients with a mean follow-up of 17 years, and Czaplicki and colleagues (1998) noted decreasing continence rates from 77% at 1 year to 57% at 5 years to 28% at 10 years, with a mean duration of continence of 78.5 months. There are significant limitations to the data because most series are retrospective, with preoperative assessment based mainly on history and physical examination and few studies using objective data as outcome measures.

Complications occur in up to 21% of cases (Mainprize and Drutz, 1988), and the placement of sutures through the pubic symphysis incurs the risk of osteitis pubis, a potentially devastating complication of the MMK procedure that has been reported in 0.9% to 3.2% of patients (Lee et al, 1979; Mainprize and Drutz, 1988; Zorzos and Paterson, 1996). Patients usually are seen 1 to 8 weeks postoperatively with acute pubic pain radiating to the inner thighs, aggravated by moving. Physical examination reveals tenderness over the pubic symphysis, and radiography demonstrates haziness to the borders of the pubic symphysis and possibly lytic changes. Treatment is with bed rest, analgesics, and possibly corticosteroids (Lee et al, 1979). Other specific complications of the MMK procedure have included the occasional erosion of nonabsorbable cystourethropexy sutures into the bladder lumen with stone formation. Also, the positioning of sutures in the endopelvic fascia close to the bladder neck can result in a significant outlet obstruction.

Whereas the MMK procedure produces a cure rate similar to that of colposuspension, the complication of osteitis pubis means that there is little to support its use as an alternative to other colposuspension procedures. Indeed the ICI committee (Smith et al, 2009) concluded that although short-term results indicate comparable cure rates to colposuspension, there is limited evidence that the longer-term outcome is poorer after MMK (evidence level 1) and declines further over time (evidence level 3). There is no evidence to support the continued use of MMK over colposuspension.

BURCH COLPOSUSPENSION

Technique

Burch's original description of the colposuspension in 1961 followed his original procedure, which was essentially a paravaginal repair attaching the paravaginal fascia to the white line of the pelvis, the arcus tendineus. The Burch colposuspension was a novel approach to restore the urethrovesical junction to a retropubic location by approximating the periurethral fascia to the tough bands of fibrous tissue running along the superior aspect of the pubic bone (Cooper [iliopectineal] ligament) with three pairs of sutures. The original Burch retropubic colposuspension is appropriate only if the patient has adequate vaginal mobility and capacity to allow the lateral vaginal fornices to be elevated toward and approximated to the Cooper ligament on either side. This technique has been modified. Tanagho's modification (1978) approximated the vaginal wall to the lateral pelvic wall, with the sutures holding the anterior vaginal wall to the Cooper ligament being tied loosely so that two fingers could be placed between the symphysis and urethra. This achieved broad support for the urethra and bladder neck and potentially minimized the risk of postoperative voiding dysfunction. A more recent modification (Shull and Baden, 1989; Turner-Warwick and Chapple, 2002) involves a hybrid approach whereby the vaginal tissues are approximated to the internal obturator fascia with an anchoring bite to the iliopectineal ligament (see VOS repair, later).

Suture placement is facilitated by the elevation of the dissected anterolateral vaginal wall into the field by the surgeon's left vaginal-examining fingers (Fig. 82-4). The bladder is retracted to the opposite side with a mounted swab. Two to four sutures are placed on each side, each suture taking a good bite of fascia and vaginal wall, with care taken not to pass through the vaginal mucosa. Some recommend taking double bites of tissue to lessen the risk of suture pull-through (Jarvis, 1994a). The most distal suture is at the level of the bladder neck and placed no closer than 2 cm lateral to it, although some place distal sutures at the mid-urethral level (Tanagho, 1978). The suspension suture bites of the paraurethral fascia should not be positioned too close to the bladder neck and the urethra, as they are in the cystourethropexy procedures (MMK), because the unwanted effect of lateral traction-tension created by their anchorage to the iliopectineal ligaments may increase the sphincteric occlusive effect on the urethra or create a degree of obstructed voiding. Subsequent sutures are placed proximal to the level of the bladder neck, at about 1-cm intervals. The sutures are then placed into corresponding sites in the Cooper ligament, the emphasis being on a mediolateral direction for the sutures. The exact mechanism of continence of the Burch procedure is still unknown. Burch (1968) thought it to be secondary to elevation and stabilization of the bladder neck and urethra. In support of the suggestion regarding suture placement, Digesu and colleagues (2004) reviewed magnetic resonance imaging findings before and 1 year after open Burch colposuspension (OBC) in 28 women to see if this would explain the mechanism. In the 86% who were cured, the distance between the levator ani muscle and bladder neck was significantly shorter than in those in whom treatment failed. Digesu's suggestion is that insertion of sutures in a medial-lateral direction as opposed to an anterior-posterior direction may better appose the levator ani muscle and bladder neck. The highly vascular vaginal wall may bleed profusely during suture placement, and large vaginal veins often need to be oversewn, but most bleeding ceases once the sutures are tied and the vagina is suspended. To facilitate tying of the sutures, the assistant elevates the appropriate portion of the vaginal wall as each suture is tied, commencing with the more distant pair.

No attempt should be made to tie the sutures tightly. Often the vaginal wall does not approximate to the Cooper ligaments, and free suture material is seen between the vagina and the ligaments. The principle is to approximate the vaginal wall to the lateral pelvic wall, where it will heal and promote adhesion formation (Tanagho, 1978; Shull and Baden, 1989; Turner-Warwick

KEY POINT: RECOMMENDATION FROM THE INTERNATIONAL CONSULTATION ON INCONTINENCE COMMITTEE (SMITH ET AL, 2009)

- The MMK procedure is not recommended for the treatment of SUI (grade A recommendation).

Figure 82-4. A, The use of a finger in the vagina when the pelvic tissues are dissected supero-medially off the vagina. B, Medial suture placement; note the role of the finger in steering the suture (*inset*). C, Note the mediolateral orientation of the sutures. D, Completion of a retropubic colposuspension with a vagino-obturator hitch on the left and a Burch procedure on the right. (From Turner-Warwick R, Chapple CR. Functional reconstruction of the urinary tract and gynaeco-urology: an exposition of functional principles and surgical procedures. Oxford [UK]: Blackwell Science; 2002.)

and Chapple, 2002), thereby creating a broad support for the urethra and bladder neck.

Results

As in the MMK procedure, short- and medium-term outcomes with the Burch procedure have been good. In [Jarvis's meta-analysis \(1994b\)](#), subjective continence was achieved in 91% (range 63% to 97%) of more than 1300 patients with 3 to 72 months of follow-up and objective continence in 84% of more than 1700 patients with 1 to 60 months of follow-up. [Lapitan and associates \(2003\)](#) reviewed 33 trials involving a total of 2403 women who underwent open colposuspension and found an overall cure rate of 68.9% to 88.0%, with a 1-year cure rate of approximately 85% to 90%. This decreased to 70% at 5 years. Although there may be a decline in the cure rate of only 15% to 20% beyond 5 years, [Alcalay and colleagues \(1995\)](#) noted a subjective and objective SUI cure rate of 69% with a mean follow-up of 13.8 years. [Baessler and Stanton \(2004\)](#) examined the impact of surgery on coital incontinence. Of the 30 women available for postoperative evaluation, 73% preoperatively had incontinence with penetration, 10% with orgasm only, and 17% with both. Postoperatively, 70% were cured of their coital incontinence. Moreover, in those who were subjectively cured of their stress incontinence, 87% were also cured of their coital incontinence.

[Lapitan and Cody \(2012\)](#) updated the Cochrane Collaboration review on open retropubic colposuspension for urinary incontinence in women. They reviewed 53 trials, including a total of 5244 women, and noted that the overall cure rate was 68.9% to 88.0% for open retropubic colposuspension. Two small studies suggested lower continence rates compared with conservative treatment; one trial suggested lower continence rates after open retropubic colposuspension compared with anticholinergic treatment. The evidence accrued from 6 trials showed a lower incontinence rate after open retropubic colposuspension than after anterior colporrhaphy, with these benefits being maintained over time. Evidence was obtained from 20 trials in comparison with suburethral slings, transvaginal tape, or transobturator tape, and these found no significant differences in incontinence rates in all time periods assessed. In comparison with needle suspension, there was a lower incontinence rate after colposuspension in the first year after surgery (RR 0.66, 95% CI 0.42 to 1.03), after the first year (RR 0.48, 95% CI 0.33 to 0.71), and beyond 5 years (RR 0.32, 95% CI 0.15 to 0.71). The patient-reported continence rates at short-, medium-, and long-term follow-up showed no significant difference between open and laparoscopic retropubic colposuspension, but with wide CIs. In 2 trials, incontinence was less common after Burch colposuspension than after the MMK procedure at 1- to 5-year follow-up. There were few data at any other follow-up time. The general finding was that the evidence did not show a higher morbidity or complication rate with open retropubic colposuspension compared with the other open surgical techniques, although pelvic organ prolapse (POP) was much more common than after anterior colporrhaphy and sling procedures. The authors concluded that open retropubic colposuspension is an effective treatment modality for SUI in the longer term. Within the first year of treatment the overall continence rate is approximately 85% to 90%. After 5 years approximately 70% of patients can expect to be dry. Laparoscopic colposuspension should allow speedier recovery, but its relative safety and long-term efficacy remain to be established.

Unlike with the MMK procedure, the good results with the Burch procedure appear to be durable with longer follow-up. [Lapitan and associates \(2003\)](#) reached the conclusion from a review of two trials comparing the Burch colposuspension and the MMK procedure that the Burch technique results in higher cure rates. Thus, it should be regarded as the *standard* open retropubic colposuspension procedure.

Open colposuspension is as effective as any other procedure in primary or secondary surgery at curing SUI with proven long-term success (level 1 evidence, grade A recommendation) ([Smith et al, 2005](#)).

Prophylactic Colposuspension

In 2006, the Colpopexy and Urinary Reduction Efforts (CARE) trial demonstrated that the **postoperative risk of stress incontinence in stress continent women undergoing open abdominal sacrocolpopexy could be substantially reduced by the addition of a Burch colposuspension** ([Brubaker et al, 2006](#)). Initial results at 3 months postprocedure demonstrated reduction of de novo stress incontinence from 44% in the untreated group to 24% in the Burch group, without increased rates of voiding dysfunction or urgency symptoms. Subsequent 1- and 2-year outcomes from the CARE trial showed continued benefit in patients who received the concomitant Burch procedure ([Burgio et al, 2007](#); [Brubaker et al, 2008](#)).

[Costantini and colleagues \(2012\)](#) reported on POP repair with and without concomitant Burch colposuspension in incontinent women in an RCT with at least 5 years' follow-up. This study was an update of a previously published trial on the impact of Burch colposuspension as an anti-incontinence procedure in patients with urinary incontinence and POP. Forty-seven women were randomly assigned to abdominal POP surgery and concomitant Burch colposuspension (24 patients) or POP surgery alone without any anti-incontinence surgery (23 patients). The median follow-up was 82 months (range 60 to 107). From 47 patients, 30 reached 6-year follow-up and 2 patients were lost to follow-up. In the first group, undergoing both POP and Burch colposuspension, 2 patients showed a stage 1 rectocele. In the second group, 2 patients had a stage 1 rectocele and 1 a stage 2 rectocele. In the first group, 13 out of 23 were still incontinent after surgery (56.5%) compared with 9 out of 22 (40.9%) of those who underwent only prolapse surgery. There was no significant change over time from the original assessment of this group. The authors concluded that Burch colposuspension did not improve outcomes significantly in incontinent patients when they were undergoing POP repair.

Reoperative Surgery

Poorer results are likely to occur when the procedure is performed secondarily. Scarring and fibrosis from previous surgery can prevent adequate suspension in some cases, and suture cut-through is more likely. Furthermore, after failed surgery, patients may have coexisting sphincteric weakness that places them at greater risk of recurrence after colposuspension ([Bowen et al, 1989](#); [Koonings et al, 1990](#)).

Nevertheless, [Maher and colleagues \(1999\)](#) and [Cardozo and associates \(1999\)](#) have both shown good objective (72% and 79%) and subjective (89% and 80%) success with repeated colposuspension at a mean follow-up of 9 months. [Nitahara and coworkers \(1999\)](#) reported 69% subjective success at a mean follow-up of 6.9 years. Urge incontinence and sphincteric weakness are the main causes of failure and dissatisfaction. Urge incontinence accounted for 63% (12 of 19) of failures; the remaining 7 with persistent stress incontinence in Nitahara's series demonstrated sphincteric deficiency with mean Valsalva leak point pressures of 65 cm H₂O. The low-pressure urethra has often been quoted to be an adverse risk factor for colposuspension ([Haab et al, 1996](#); [Bowen et al, 1989](#); [Koonings et al, 1990](#)), but this topic also remains controversial. Several authors have studied the urethral pressure profilometry changes after colposuspension and have noted a statistically significant increase in the postoperative pressure transmission ratio but minimal changes in the postoperative MUCP, functional urethral length, and continence area ([Faysal et al, 1981](#); [Weil et al, 1984](#); [Feyersiel et al, 1994](#)). Although a low-pressure urethra (MUCP <20 cm H₂O) is considered a contraindication to the Burch procedure, a modification of the standard Burch operation has had some success in managing SUI associated with the low-pressure urethra. [Bergman and colleagues \(1989c\)](#) combined a standard Burch procedure with the Ball procedure ([Ball, 1963](#)) wherein before the Cooper ligament suspension is performed, two or three sutures are used to plicate the anterior urethral wall at the level of the proximal and middle urethra. These researchers retrospectively noted greater

success with this technique than with a standard Burch procedure for the low-pressure urethra, and this was comparable to the success obtained with a standard Burch procedure in patients with a normal-pressure urethra (MUCP >20 cm H₂O). With longer follow-up, the Ball-Burch procedure continued to yield better results than the standard Burch procedure in patients with a low-pressure urethra, with a documented 5-year cure rate of SUI of 84% (Bergman et al, 1991; Elia and Bergman, 1995). However, there are no randomized studies addressing the issue, and whether these results can be extrapolated for the use of this technique in patients with intrinsic sphincter deficiency is debatable.

Giarenis and colleagues (2012) pose the question of what to do when a mid-urethral tape fails, emphasizing the potential role of open colposuspension as a salvage continence procedure. This was a retrospective study of 13 women who had undergone open colposuspension after a failed mid-urethral sling. The average time between insertion of the mid-urethral tape and the colposuspension was 22.6 (range 8 to 72) months. The mean operating time was 77 (range 43 to 123) minutes, including the time for the concomitant surgery. The mid-urethral tape was identified and partially excised. The authors reported a median follow-up of 12 months. Subjective and objective cure rates were 85% and 77%, respectively. Only 1 woman had severe SUI postoperatively, requiring further surgery. Three of the 8 women with preexisting urinary urgency reported postoperative improvement. Two patients reported de novo urinary urgency and urgency incontinence. Three of 10 women developed de novo detrusor overactivity that responded to anticholinergic medication. Long-term voiding difficulty was observed in only 1 patient, who performed clean intermittent catheterization for 3 months. No patients developed recurrent urinary incontinence. Three women (23%) developed symptomatic prolapse postoperatively. These patients were at stage II on the Pelvic Organ Prolapse Quantification System (POP-Q) scale involving the posterior vaginal compartment and underwent posterior repair within 22 months of colposuspension. Bearing in mind that this is a small series, nevertheless it raises the point that, allowing for the fact that there is morbidity associated with a colposuspension in this context, it is still a potential therapeutic option in these patients.

A recent Cochrane meta-analysis has looked at the evidence for the treatment of recurrent SUI after failed minimally invasive synthetic suburethral tape surgery in women (Bakali et al, 2013). Twelve studies were identified, but all were excluded because they did not meet the eligibility criteria. Six were RCTs but were not eligible because the previous incontinence surgery had not been a suburethral tape. A subset of one RCT may have been eligible for inclusion because one of the women was having repeat surgery, but the authors were unable to obtain the data according to primary surgery for this cohort from the authors of the original study. The question of how to best deal with recurrent stress incontinence after a tape procedure will depend on whether the primary problem is that of intrinsic sphincter deficiency or problems with repositioning the urethra, and the question as to whether colposuspension may have a role in this context still remains open on the basis of this review of the literature because there is no clear evidence-based conclusion available.

Conversely, Shao and colleagues (2011) reported on TVT retropubic sling for recurrent SUI after Burch colposuspension failure. In this small series of 24 women undergoing TVT procedures for recurrent stress incontinence after a previous failed Burch colposuspension, the median follow-up was 57 months (range 12 to 96 months). Preoperative and postoperative urethral mobility and urodynamics were evaluated. It was noted that preoperatively in all women there was intrinsic sphincter deficiency, and 14 had urethral hypermobility. Postoperatively, 15 patients were completely dry, and 2 had a leakage of urine less than 5 g/hr. The overall success rate was 70.8% and there was a significant postoperative increase of MUCP and a decrease of average flow rates and average hypermobility. The authors concluded that recurrent SUI after a Burch colposuspension can be successfully treated with a TVT procedure. This, however, needs to be considered cautiously as a conclusion, because in the context of intrinsic sphincter defi-

ciency, many authors in contemporary practice would express concern about putting in such a sling under any degree of tension to correct intrinsic sphincter deficiency because of the long-term potential complications with sling exposure that may occur. In this context, the potential use of an autologous sling should be carefully considered.

As with any major abdominal or pelvic surgical procedure, intra-operative and perioperative complications that may occur after a retropubic suspension include bleeding, injury to genitourinary organs (bladder, urethra, ureter), pulmonary atelectasis and infection, wound infection or dehiscence, abscess formation, and venous thrombosis or embolism. Other complications more specific to retropubic suspension procedures include postoperative voiding difficulty, detrusor overactivity, and vaginal prolapse. These are discussed in more detail along with other reported complications in a later section in this chapter.

KEY POINTS: RECOMMENDATIONS FROM THE INTERNATIONAL CONSULTATION ON INCONTINENCE COMMITTEE (SMITH ET AL, 2009)

- Open retropubic colposuspension can be recommended as an effective treatment for primary SUI, which has longevity (grade A recommendation).
- Although open colposuspension has to a large extent been superseded by the less invasive mid-urethral tapes, it should still be considered for those women in whom an open abdominal procedure is required concurrently with surgery for SUI (grade D recommendation).

PARAVAGINAL REPAIR

Technique

The origins of the paravaginal repair date to White (1912, 1997), who described the importance of the “white line” of the pelvis (arcus tendineus) as an integral structure supporting the proximal urethra and bladder base to the pelvic wall and the development of paravaginal fascial tears predisposing to cystocele formation. He performed the paravaginal repair by a vaginal approach but envisioned that it would be easier if performed abdominally (White, 1912, 1997). Later, in his original description, Burch attached the vaginal wall to the arcus tendineus in seven patients, only to realize that the attachment may not be secure, prompting him to use the Cooper ligament as an attachment site (Burch, 1961). In the 1970s, Richardson and coworkers (1976) reintroduced the concept of a lateral defect cystourethrocele as a causative factor in the genesis of SUI and popularized the paravaginal repair as a technique for management.

The patient is placed in a low lithotomy position, just as for the MMK procedure and Burch colposuspension. If there are retropubic adhesions resulting from prior surgery, they are sharply incised; the dissection is facilitated by placement of two fingers of the surgeon's left hand in the vagina. The bladder and urethra are not mobilized from the vaginal attachments. Richardson and colleagues (1981) describe an extensive reattachment of the lateral vaginal sulcus with its overlying fascia to the arcus tendineus fasciae pelvis from the back of the lower edge of the symphysis pubis to the ischial spine, using six to eight sutures placed at 1-cm intervals. The vaginal wall in the region of the bladder neck is identified, and these interrupted sutures are placed at approximately 1-cm intervals through the paravaginal fascia and vaginal wall (excluding vaginal mucosa) beginning at the urethrovaginal junction. The sutures are then passed through the adjacent obturator fascia and underlying muscle at the site of the arcus tendineus fascia (Fig. 82-5). If the arcus is

Figure 82-5. A paravaginal repair procedure.

not visible, the obturator foramen may be used as a landmark. It is situated 1.5 to 2 cm above the white line.

The end point that should be achieved is the reestablishment of the urethral axis in an anatomic position, easily allowing three fingerbreadths between the pubic symphysis and the proximal urethra but providing secure fixation and preventing rotational descent. Consequently, it has been reported that postoperative voiding difficulties are uncommon (Richardson et al, 1981).

Results

Few reports on the use of this technique have been published. With variable follow-up, cure rates greater than 90% have been reported for the paravaginal repair (Richardson et al, 1981; Shull and Baden, 1989). There is only a single randomized comparison of colposuspension with paravaginal repair including 36 patients who were randomly allocated to treatment by either colposuspension or paravaginal repair with nonabsorbable suture material. At 6 months of follow-up, there was an objective cure rate of 100% for those undergoing colposuspension and 72% for those undergoing paravaginal repair (Colombo et al, 1996a).

Small series have reported on vaginal approach to paravaginal repairs (Scotti et al, 1998; Mallipeddi et al, 2001). In particular, Mallipeddi and colleagues followed 45 patients (21 with SUI) after this approach for a mean of 1.6 years, and 57% had persistent stress incontinence; the conclusion of these researchers was that this technique had limited applicability for SUI. It can be concluded that there is level 1 or 2 evidence that abdominal paravaginal repair is less effective than colposuspension. There are limited data (level 3 or 4) on laparoscopic and vaginal paravaginal repairs, but interpretation of these data is hampered by the small numbers of patients, the short follow-up, and a combination of this procedure with other types of incontinence procedures (Smith et al, 2005).

There is limited evidence that abdominal paravaginal defect repair is less effective than open colposuspension (evidence level 2) (Smith et al, 2009).

VAGINO-OBTURATOR SHELF REPAIR

Technique

Turner-Warwick (1986; Turner-Warwick and Chapple, 2002) reported his variant of the paravaginal repair, which he called the *vagino-obturator shelf repair*. The premise for this is that there should

KEY POINT: RECOMMENDATION FROM THE INTERNATIONAL CONSULTATION ON INCONTINENCE COMMITTEE (SMITH ET AL, 2009)

- Paravaginal defect repair is not recommended for the treatment of SUI alone (grade A recommendation).

be no restriction to the intrinsic sphincteric function of the urethra by fixation or paraurethral tethering, and there should be no urethral compression (Turner-Warwick and Kirby, 1993).

Just as for other retropubic suspension procedures (Fig. 82-6), the anterior wall of the lower segment of the bladder wall is exposed and the position of the bladder neck is identified by gentle traction on a balloon catheter in the urethra. The surgeon's forefinger in the vagina elevates its anterior wall and the overlying endopelvic fascia on either side of the urethra. Lateral displacement of the catheter balloon with the finger in the vagina facilitates the identification of the inferolateral margin of the bladder, lateral to the bladder neck, and its separation from the paraurethral endopelvic fascia is achieved by simple blunt dissection with a sponge or scissor-tip retraction. This naturally exposes the surface of the obturator muscle and the arcus tendineus origin of the levator muscles deep in the sulcus below this, the site of suture placement in the paravaginal repair (which is well below the vaginal anchorage point in the VOS procedure). The obturator nerves lie superolaterally; their canals run high up in a groove under the superior pubic ramus so that once they have been identified, injury to them can be avoided. The full thickness of the vagina and its overlying layer of endopelvic fascia are elevated by the surgeon's finger in the vagina and are approximated to the internal obturator muscle and anchored to the bulk of this with absorbable 0 or No. 1 sutures mounted on robust 35- to 40-mm half-circle needles. Slight flexion of the fingertip tents the vaginal wall and facilitates the full-thickness insertion of these suture bites through it, thus avoiding inclusion of the surgical glove. Three or four successive sutures are inserted. For knot security, these are best tied continuously, head to tail, as they are inserted, rather than separating them individually. Each tied suture bite facilitates the insertion of the next (unlike in the Burch procedure, in which the sutures are not tied until they have all been inserted). A similar obturator suspension of the elevated protrusion of the vagina and its overlying endopelvic fascia is achieved on the opposite side. Some additional elevation of the lateral anchorage of the VOS by the inclusion of a bite of the iliopectineal ligament within the suture bite approximating the vagina to the obturator muscle (as in a Burch procedure) may be used to reinforce the repair (Shull and Baden, 1989). This modification is one that I favor and represents a hybrid with the Burch procedure, facilitating reattachment of the pubocervical fascia to the arcus tendineus fasciae pelvis, tissue apposition to the lateral pelvic wall, and nonobstructive elevation of the urethra and urethrovesical junction. In addition, obliteration of the pouch of Douglas (culdoplasty) may be needed to prevent enterocele (Shull and Baden, 1989; Turner-Warwick and Kirby, 1993).

Results

There are limited data available for the VOS repair, which has had reported cure rates of 60% to 86%, depending on whether the procedure was performed primarily or secondarily (Turner-Warwick, 1986; German et al, 1994). German and colleagues (1994) reported that the VOS procedure is less likely to be successful in patients who have undergone previous surgery.

Ultimately, as with all such reconstructive surgery, the surgeon should select the correct procedure for the individual patient. Although the VOS, which is a synthesis of the principles of the paravaginal repair and the Burch colposuspension, is of interest, further clinical results are necessary before definitive conclusions can be drawn.

Figure 82-6. A, Mobilizing the tissues. The tissues should be stripped by blunt dissection with a mounted swab or the edge of a pair of scissors; only occasionally is sharp dissection necessary, provided the stripping action starts far laterally adjacent to the pubic bone. B, Completed vagino-obturator shelf procedure. (From Turner-Warwick R, Chapple CR. *Functional reconstruction of the urinary tract and gynaeco-urology: an exposition of functional principles and surgical procedures*. Oxford [UK]: Blackwell Science; 2002.)

LAPAROSCOPIC RETROPUBIC SUSPENSION

Laparoscopic techniques for retropubic suspension were introduced by [Vancaillie and Schuessler in 1991](#). They essentially performed an MMK urethropexy laparoscopically, and since that time, laparoscopic techniques have been applied to both the Burch procedure and the paravaginal repair. Subsequent modifications to the suspension suturing techniques have been introduced, including the use of mesh ([Ou et al, 1993](#)), staples ([Lyons, 1994](#)), and fibrin sealant ([Kiilholma et al, 1995](#)), but all adhere to the same principles of their open counterparts. Proposed advantages of the laparoscopic approach include improved intraoperative visualization, less post-operative pain, shorter hospitalization, and quicker recovery times ([Liu, 1993](#)). Disadvantages include greater technical difficulty with resultant longer operating times and higher operating costs ([Paraíso et al, 1999](#)).

The procedure may be performed extraperitoneally or transperitoneally, and each approach has its proponents. Although the extraperitoneal technique may be associated with shorter operating times, easier dissection, and fewer bladder injuries ([Frankel and Kantipong, 1993](#); [Raboy et al, 1995](#)), the transperitoneal approach provides a larger operating space and the ability to perform concomitant intraperitoneal procedures and apical prolapse repair ([Paraíso et al, 1999](#)). The specifics of the different procedures are beyond the scope of this chapter.

Short- and medium-term outcomes with the laparoscopic retropubic suspensions have become available. In their review of 13 studies of laparoscopic retropubic suspensions, [Paraíso and colleagues \(1999\)](#) found cure rates to range from 69% to 100% with follow-up of 1 to 36 months. This is comparable to outcomes of the open procedures as already noted. Both retrospective ([Polascik et al, 1995](#)) and randomized, prospective comparisons ([Summitt et al, 2000](#)) between open and laparoscopic techniques have demonstrated similar short-term success. However, with longer follow-up, laparoscopic retropubic suspensions appear to fail more frequently. [McDougall's group \(1999\)](#) retrospectively noted only 30% cure of SUI and 50% cure or improvement after a laparoscopic

Burch procedure with 45 months of follow-up, and this was no different from the results with a Raz procedure.

Five trials summarized in a Cochrane review have compared laparoscopic with open colposuspension ([Burton, 1997](#); [Su et al, 1997](#); [Burton, 1999](#); [Carey et al, 2000](#); [Summitt et al, 2000](#); [Fatthy et al, 2001](#); [Moehrer et al, 2002](#)). All had different lengths of follow-up: 6 months ([Carey et al, 2000](#)); 1 year ([Su et al, 1997](#); [Summitt et al, 2000](#)); 6 and 18 months ([Fatthy et al, 2001](#)); and 6 months, 1 year, 3 years, and 5 years ([Burton, 1997, 1999](#)). Outcome data for 6 months to 18 months were therefore available for all studies. Longer-term data are currently available only for Burton's study. The ability to synthesize data was also limited by the variable tests and definitions used to measure subjective and objective outcomes across the trials ([Moehrer et al, 2003](#)). Moehrer and colleagues, in their meta-analysis, noted that a total of 233 women received a laparoscopic and 254 women an open colposuspension, and the CIs are generally all wide as a consequence. Four trials comparing laparoscopic with open colposuspension were otherwise of good quality ([Burton, 1997, 1999](#); [Carey et al, 2000](#); [Summitt et al, 2000](#); [Fatthy et al, 2001](#)). Burton's study had the potentially confounding factors of use of absorbable sutures and of the surgeon's having carried out only a relatively small number of laparoscopic colposuspensions (<20) before commencing the trial. These factors may have influenced his results, in particular because there is believed to be a definite albeit relatively steep learning curve associated with laparoscopic colposuspensions. The fifth trial had methodologic problems with corrupted randomization and confounding factors of performance of additional surgery in some patients and the use of a different number of sutures for laparoscopic (one suture) and open (three sutures) colposuspension ([Su et al, 1997](#)). The number of sutures used appears to have a significant influence on the cure rate, with more sutures resulting in a significantly higher success rate. [Persson and Wolner-Hanssen \(2000\)](#) compared different numbers of paravaginal sutures and found a significantly higher objective 1-year cure rate (dry on "ultra-short" pad test) for women randomized to two sutures compared with one suture, with a cure rate of 83% for two sutures and 58%

for one suture. Only one trial currently has data beyond 18 months of follow-up (Burton, 1997, 1999). This suggested poorer long-term results after laparoscopic surgery. This finding should be interpreted cautiously, however, as there are concerns that the surgeon's laparoscopic performance may have been suboptimal because he had performed few laparoscopic colposuspensions when the trial started. Data from other larger trials with multiple operators are now needed to assess whether this is a real effect. All the other trials had data up to a maximum of 18 months. These show some inconsistencies. Outcome assessed by the women participating (arguably the most important outcome) appeared equally good in the two groups. Urodynamic investigations were used to assess cure objectively in all five studies. Overall, there was a significantly higher success rate after open colposuspension (RR 0.89, 95% CI 0.82 to 0.98), equivalent to an absolute difference of an additional 9% risk of failure after laparoscopic surgery. No significant differences between the two groups were observed for postoperative urgency, voiding dysfunction, or de novo detrusor overactivity. A trend was shown toward a higher complication rate, less postoperative pain, shorter hospital stay, and more rapid return to normal function for laparoscopic colposuspension. The operating time tended to be longer, the intraoperative blood loss less, and the duration of catheterization shorter for laparoscopic compared with open colposuspension (Moehrer et al, 2003).

In a review of laparoscopic colposuspension, Paraiso and colleagues (1999) noted major intraoperative and short-term complications in up to 25% of cases, with bladder injury being the most common complication and declining with experience; ureteric injury has also been reported (Aslan and Woo, 1997). The use of mesh and tacks or staples may be complicated by foreign body erosion (Arunkalaivanan and Smith, 2002; Kenton et al, 2002), and a randomized study (Ankardal et al, 2004) reported that the use of sutures was superior to the laparoscopic mesh and staple technique.

A previous Cochrane review (Moehrer et al, 2002) was dependent on small trials, recruiting a total of 487 women among them, with mostly only medium-term follow-up data (18 months) and limited evidence from other small studies and concluded that laparoscopic colposuspension had the benefit of a more rapid recovery but might have a higher complication rate, be more expensive, and possibly be less effective in the long term than open colposuspension. This highlighted the need for further well-designed clinical studies.

Carey and coworkers (2006) reported a randomized trial that recruited 200 women during 1997 and 1998, with 2-year follow-up available for 83% of participants and longer-term subjective data from a similar proportion. The primary outcome measure was objective cure (absence of urodynamic stress incontinence) at 6 months, powered to detect a difference of 20% between the two arms. Secondary measures included patient satisfaction, quality of life and general well-being, and complications. In the same year Kitchener and colleagues (2006) reported the results of the COLPO trial, which recruited 291 women in 1999 to 2001, with a 2-year follow-up rate of more than 80%. The primary outcomes were objective (dry pad test) and subjective (symptom report) cure at 24 months. Secondary outcomes included recovery time, complications, and a formal cost-benefit analysis. The trial was powered to show noninferiority of laparoscopic colposuspension to open colposuspension, assuming a cure rate of 80% for the open procedure. Both studies were well designed, well conducted, and clearly reported.

Carey and colleagues found no difference in urodynamic cure rate, incidence of detrusor overactivity, or patient satisfaction at 6 months, with an overall objective cure rate of 75%. Detrusor overactivity occurred in 12% of women, and 66% of women were urodynamically normal. If the raw data are converted to percentage scores, there was 89% satisfaction with the treatment outcomes and 88% satisfaction with the care received. The overall satisfaction was 87%. At 24 months after surgery, there were no significant differences between the two treatment groups with respect to reporting urinary stress incontinence, urgency, urgency incontinence, or sat-

isfaction score of 80 or higher. Across both treatment groups, by 24 months after surgery, 66% of women reported no stress incontinence, 38% reported no urgency, 47% reported no urgency incontinence, and 64% reported a satisfaction score of 80 or higher. Although follow-up information was available for only approximately 80% of all subjects by 24 months, a sensitivity analysis was performed assuming that all women who did not complete the 24-month follow-up had either occasional or frequent stress incontinence. With these assumptions, cure rates decreased to 61% for open colposuspension and 50% for laparoscopic colposuspension. There was no significant difference between the two treatment groups, even when adjusted for surgeon experience ($P = .08$). The study population was contacted by telephone for further follow-up at a mean of 3.7 years (range 3 to 5 years) after surgery. This follow-up was undertaken at a single point in time. A total of 162 women were contacted, 88 of whom had undergone open colposuspension and 76 of whom had undergone laparoscopic colposuspension. There were no significant differences between the two treatment groups at 3 to 5 years after surgery, and the findings were similar to the 24-month data. Mean operating time was approximately twice as long for laparoscopic colposuspension, but surgeons' estimates of blood loss and patients' estimates of immediate postoperative pain at rest were significantly less after the laparoscopic procedure, with a return to normal activities, on average, 5 days earlier ($P = .01$).

Kitchener and colleagues also found no difference in the objective cure rate (79% for laparoscopic vs. 70% for open) or subjective cure rate (55% vs. 54%) between the study arms, again showing the now well-recognized mismatch between objective and subjective outcomes. The intention-to-treat analysis indicated no significant difference in cure rates between open and laparoscopic surgery. The study was slightly underpowered based on the sample size calculations, but the analyses clearly demonstrated that laparoscopic colposuspension is not inferior to open colposuspension. The complication rate was low in both arms, with more bowel and bladder injuries in the laparoscopic arm and more wound infections in the open arm. Each demonstrated comparable improvements in generic quality-of-life scores. Other points of note included the careful selection of surgeons who had experience with both open and laparoscopic surgery and, it is interesting to note, findings that were in contrast to the Carey study and contrary to the previously held beliefs that laparoscopic surgery would be associated with longer operating times, less postoperative pain, and shorter hospital stay. For hospital stay, there was only a small advantage for laparoscopic surgery, with a median stay of 5 days compared with 6 for open surgery. The operating times were fairly similar in terms of "knife to skin" to completion of surgery—median times of 65 and 51 minutes for laparoscopic and open surgery, respectively. Postoperative pain was significantly less in the laparoscopic surgery group. There were no differences in time of return to work identified in this study. Complications of surgery were low in general, with a higher bladder injury rate for the laparoscopic procedure and a higher wound infection rate for open surgery, as would be expected. The impact of these differences was analyzed in a cost-benefit analysis accompanying this study, which suggested that a greater quality-adjusted life year total is achieved in the laparoscopic arm at both 6 and 24 months, suggesting that laparoscopic surgery may confer an additional benefit of well-being (Manca et al, 2006). However, the additional costs of laparoscopic surgery were recouped only after 24 months of follow-up, thus highlighting the need to address long-term outcomes in any surgical study.

The last major publication in this field was a meta-analysis of all of the comparative studies published from 1995 to 2006 of laparoscopic versus open colposuspension (Tan et al, 2007). End points evaluated were operative outcomes and subjective and objective cure. A random-effect model was used and sensitivity analysis performed to account for bias in patient selection. Sixteen studies matched the selection criteria, reporting on 1807 patients, of whom 861 (47.6%) underwent laparoscopic and 946 (52.4%) underwent open colposuspension. Length of hospital stay and return to

normal life were significantly reduced after laparoscopic surgery. These findings remained consistent on sensitivity analysis. Bladder injuries occurred more often in the laparoscopic group, but only with marginal statistical significance. Comparable bladder injury rates were found when studies were matched for quality, year, and randomized trials. Cure rates were similar between the two procedures at 2 years of follow-up.

The current evidence would suggest that in adequately experienced hands there is no difference in overall safety and efficacy between laparoscopic and open colposuspension. Clearly another concern is how generalizable the data on laparoscopic colposuspension are, because the majority of reported studies are from expert laparoscopists or surgeons working in specialized units. The evidence base for both laparoscopic and open colposuspension is limited by relatively short-term follow-up; robust data out to 5 years are needed. The tendency toward small numbers and poor methodology limits the interpretation of most studies, with the exception of those reported by Carey and colleagues (2006) and Kitchener and colleagues (2006). Laparoscopic colposuspension shows comparable subjective outcome but poorer objective outcome than both open colposuspension and TVT in the short to medium term; longer-term outcomes are unknown (evidence level 2). Laparoscopic colposuspension may not offer good value for money when compared with open colposuspension in the short term (i.e., first 6 months after surgery), but it could be a cost-effective alternative over 24 months (evidence level 1); other comparisons, however, suggest that minimally invasive mid-urethral tape procedures may be superior in health economic terms.

In a review article looking at the surgical management of female SUI, the question as to what is the optimal procedure is addressed (Cox et al, 2013). The traditional gold standard procedures of Burch retropubic colposuspension and pubovaginal sling are both considered to be approved treatment options for appropriate patients. RCTs, as noted in this paper, have demonstrated that synthetic mid-urethral slings are also highly effective. Cox and colleagues (2013) concluded that retropubic mid-urethral slings are associated with slightly higher success rates than transobturator slings, but at the cost of more postoperative complications. Certainly pubovaginal slings are an effective option for women with SUI in whom other procedures have failed, and in particular if there are mesh complications that require concomitant urethral surgery. The authors concluded that both retropubic and transobturator mid-urethral slings are effective for patients with mixed urinary incontinence, but the overall cure rate is lower than for patients with pure stress incontinence. They concluded that their literature review suggests that a new gold standard first-line surgical treatment for women with SUI is a synthetic mid-urethral sling inserted through a retropubic or transobturator approach. A further study looked at the cost comparison of laparoscopic Burch colposuspension, a laparoscopic two-team sling procedure, and the transobturator tape procedure for the treatment of SUI (Lo et al, 2013). This retrospective observational study of isolated minimally invasive surgical procedures reached the conclusion that a transobturator tape procedure has lower direct medical costs than a laparoscopic Burch colposuspension or a laparoscopic two-team sling procedure. This is not surprising in view of the interventions necessary. Clearly, this has been one of the main drivers that led to the lack of progression of laparoscopic colposuspension into clinical practice, despite the availability of improved laparoscopic techniques.

Barr and colleagues (2009) looked at the long-term outcome of laparoscopic colposuspension in a report from a 10-year cohort study. A consecutive series of 139 patients who had undergone laparoscopic colposuspension was reviewed and compared with 52 women who had undergone an open colposuspension in the same unit. Subjects were contacted by telephone at least 10 years postoperatively. In total, 96 patients in the laparoscopic group and 31 in the open colposuspension group were available for follow-up. The authors reached the conclusion that laparoscopic colposuspension appeared to be as effective as open colposuspension at long-term follow-up when used as treatment for stress incontinence and could be considered as an alternative surgical approach.

KEY POINTS: RECOMMENDATIONS FROM THE INTERNATIONAL CONSULTATION ON INCONTINENCE COMMITTEE (SMITH ET AL, 2009)

- Laparoscopic colposuspension is not recommended for the routine surgical treatment of SUI in women (grade A recommendation).
- Laparoscopic colposuspension might be considered for the treatment of SUI in women who also require concurrent laparoscopic surgery for other reasons (grade D recommendation).
- Laparoscopic colposuspension should be carried out only by surgeons with specific training, expertise, and appropriate workload in laparoscopic surgery and in the assessment and management of urinary incontinence in women (grade D recommendation).

COMPLICATIONS OF RETROPUBIC REPAIRS

As with any major abdominal or pelvic surgical procedure, intraoperative and perioperative complications that may occur after a retropubic suspension include bleeding, injury to genitourinary organs (bladder, urethra, ureter), pulmonary atelectasis and infection, wound infection or dehiscence, abscess formation, and venous thrombosis or embolism. Other common complications more specific to retropubic suspension procedures include postoperative voiding difficulty, detrusor overactivity, and vaginal prolapse. Potentially, it is overcorrection of the urethrovesical angle that may be a major contributory factor in the development of the long-term complications of de novo urgency, voiding dysfunction, and enterocele formation.

Nevertheless, the reported incidence of these problems is relatively low. In their meta-analysis, Leach and associates (1997) noted a 3% to 8% transfusion rate for retropubic suspensions and no significant difference in the overall medical and surgical complication rates among retropubic suspensions, needle suspensions, anterior colporrhaphy, and pubovaginal slings. Mainprize and Drutz (1988), in their review of the MMK procedure literature (2712 patients), noted an overall complication rate of 21%, with wound complications and urinary infections making up the majority (5.5% and 3.9%, respectively). Direct surgical injury to the urinary tract occurred in only 1.6%, and genitourinary tract fistulas occurred in 0.3%. Ureteral obstruction has been reported rarely after Burch colposuspension, and it usually results from ureteral kinking after elevation of the vagina and bladder base, although direct suture ligation of the ureter can occur (Applegate et al, 1987). If it is identified intraoperatively, it is best remedied by removal of the offending ligature and temporary placement of a ureteral stent. The so-called postcolposuspension syndrome, which has been described as pain in one or both groins at the site of suspension, has been noted in up to 12% of patients after a Burch procedure (Galloway et al, 1987). More recently, Demirci and colleagues (2001) reported the occurrence of groin or suprapubic pain in 15 of 220 women (6.8%) after Burch colposuspension with a follow-up of 4.5 years.

Postoperative Voiding Difficulty

Postoperative voiding difficulty after any type of retropubic suspension is not uncommon, and undoubtedly its occurrence is more likely if there is preexisting detrusor dysfunction or denervation resulting from extensive perivesical dissection. In most cases, however, it is the result of overcorrection of the urethral axis from inappropriately placed or excessively tightened sutures. If the sutures are placed too medially, they may also transfix the urethra or distort it.

Preoperatively, at-risk patients may be identified by their history of prior voiding dysfunction or episodes of urinary retention. These women should be carefully counseled preoperatively about the

potential for postoperative voiding difficulty and the possible need for self-catheterization intermittently. Their incontinence should be of sufficient magnitude that its correction offsets the risk of the need for self-catheterization.

Women with postcystourethropey voiding problems who have obstruction often do not exhibit the classic urodynamic features of obstruction. However, the history of postoperative voiding symptoms and associated new-onset bladder storage symptoms and a finding of a retropubically angulated and fixed urethra typically indicate that obstruction does exist (Carr and Webster, 1997). In such cases, revision of the retropubic suspension by releasing the urethra into a more anatomic position resolves voiding symptoms in up to 90% of patients (Webster and Kreder, 1990; Nitti and Raz, 1994; Carr and Webster, 1997).

The meta-analysis by Leach and coworkers (1997) noted that the risk of temporary urinary retention lasting more than 4 weeks postoperatively is 5% for all retropubic suspensions, and the risk for permanent retention is estimated to be less than 5%. These risks are not significantly different from those for needle suspensions or pubovaginal slings. Mainprize and Drutz's review of the literature (1988) yielded a 3.6% incidence of postoperative voiding problems after an MMK procedure, whereas the Burch procedure literature reports an incidence of postoperative voiding disorders ranging from 3% to 32% (Hilton and Stanton, 1983; Galloway et al, 1987; Eriksen et al, 1990; Alcalay et al, 1995; Colombo et al, 1996a). In more recent literature, voiding dysfunction may be persistent, as noted in 3.5% of a series of 310 women with a mean follow-up of 36 months (Viereck et al, 2004). Non-persistent voiding dysfunction has been reported in 12.5% (6% to 37.2%) after primary surgery (Smith et al, 2005). After colposuspension conducted as a secondary procedure, Bidmead and associates (2001) reported voiding difficulties requiring intermittent self-catheterization in 6% of cases.

Because the paravaginal repair aims to restore normal anatomy, there is theoretically little chance of overcorrection of the urethral axis, which should translate into a lower risk of postoperative obstruction. In Richardson and coworkers' study (1981), 80% of patients were able to void immediately after paravaginal repair, and "all patients had satisfactory bladder function at the time of discharge." However, temporary voiding difficulty has been noted in up to 17% of patients after a VOS procedure (German et al, 1994), and chronic (>2 years) voiding difficulty has been noted in up to 11% of patients after the paravaginal repair (Colombo et al, 1996a).

All patients should be counseled before surgery about the potential need for intermittent self-catheterization.

Bladder Overactivity

Bladder overactivity commonly accompanies anatomic SUI, and its incidence preoperatively has been reported to be as high as 30% in patients undergoing either first correction or repeated operations (McGuire, 1981). Provided it is considered as a diagnosis, urodynamic evaluation has been performed to show whether detrusor overactivity is present, an attempt at treatment of the related overactive bladder symptoms has been made (with or without success), and the patient has been advised that the presence of detrusor overactivity will increase the risk of continuing storage symptoms postoperatively, then preoperative bladder overactivity does not contraindicate a retropubic suspension procedure, provided that anatomic SUI has also been demonstrated. In the majority of patients, the bladder overactivity symptoms resolve after surgical repair (McGuire, 1988). Leach and coworkers' meta-analysis (1997) found the risk of urgency after a retropubic suspension to be 66% if urgency and detrusor overactivity were present preoperatively, 36% if there was urgency but no documented overactivity preoperatively, and only 11% if there was neither urgency nor overactivity preoperatively. There was no significant difference in the incidence of postoperative urgency among retropubic suspensions, needle suspensions, and pubovaginal slings. Postoperative urgency was noted in only 0.9% of MMK procedures in Mainprize and Drutz's meta-analysis of 15 series (1988),

although Parnell and associates (1982) reported that 28.5% of their patients developed postoperative storage symptoms. Jarvis's meta-analysis (1994b) of Burch procedures found the incidence of de novo bladder overactivity to be 3.4% to 18%. More recently, Smith and colleagues (2005) quoted a figure for postoperative detrusor overactivity of 6.6% for colposuspension (range 1.0% to 16.6%), whereas the incidence of postoperative urgency or urge incontinence after the paravaginal or VOS repair has been reported to be 0% to 6% (Shull and Baden, 1989; German et al, 1994; Colombo et al, 1996a).

For patients in whom postoperative storage symptoms persist, proven to be associated with detrusor overactivity and intractable to management with anticholinergic therapy and behavioral modification, surgical techniques including intravesical botulinum toxin therapy, neuromodulation, augmentation cystoplasty, or detrusor myectomy may be indicated.

Bladder storage symptoms arising de novo after retropubic suspension may be associated with bladder outlet obstruction. This premise is supported by the frequent coexistence of these symptoms with impaired voiding after suspension procedures and confirmed by the finding that urethrolisis, by freeing the urethra from an obstructed position, often resolves both storage and voiding symptoms (Raz, 1981; Webster and Kreder, 1990).

Vaginal Prolapse

Retropubic suspensions alter vaginal and bladder base anatomy, and thus postoperative vaginal prolapse is a potential complication. Genitourinary prolapse has been reported as a sequel to Burch colposuspension in 22.1% of women (range 9.5% to 38.2%) by Smith and colleagues (2005) in their review of the literature. The Burch procedure, because of lateral vaginal elevation, may aggravate posterior vaginal wall weakness, predisposing to enterocele. The incidence varies from 3% to 17% (Burch, 1961, 1968; Galloway et al, 1987; Wiskind et al, 1992); because of this, prophylactic obliteration of the cul-de-sac of Douglas is sometimes considered in performing retropubic suspensions (Shull and Baden, 1989; Turner-Warwick and Kirby, 1993). However, simultaneous hysterectomy is not recommended prophylactically because it does not enhance the outcome of a retropubic suspension and should be performed only if there is concomitant uterine disease (Milani et al, 1985; Langer et al, 1988). Although the Burch procedure and paravaginal or VOS repair both correct lateral defect cystourethroceles, recurrent cystourethroceles have been noted in 11% and 39% of Burch procedures and paravaginal repairs, respectively (Colombo et al, 1996a). In Mainprize and Drutz's review (1988), postoperative cystocele was noted in only 0.4% of patients after an MMK procedure.

Wiskind and coworkers (1992) noted that 27% of patients who had undergone a Burch colposuspension developed prolapse requiring surgery: rectocele in 22%, enterocele in 11%, uterine prolapse in 13%, and cystocele in 2%. More recently, it has been suggested that most women are asymptomatic, and less than 5% have been reported to request further surgery (Smith et al, 2005). Ward and Hilton (2004) reported that 4.8% of women needed a posterior repair, whereas Kwon and associates (2003) reported that 4.7% required subsequent pelvic reconstruction.

Auwad and colleagues (2006) reported the findings of the first prospective study to determine the prevalence of POP after colposuspension and to investigate possible preoperative and operative risk factors. Seventy-seven women who underwent colposuspension from 1996 to 1997 were investigated. POP was assessed before colposuspension using the POP-Q. Women were reassessed at 1 and 7 to 8 years (or when referred with symptomatic POP). By 7 to 8 years, of the 77 women, 29 (38%) had developed symptomatic prolapse, 29 (38%) had asymptomatic prolapse, 7 (9%) had no symptoms and no prolapse, and 12 (16%) could not be assessed. POP at 1 year was significantly associated with the presence of posterior vaginal descent before colposuspension (odds ratio 3.07, 95% CI 1.10 to 8.60, $P = .03$). No potentially predisposing variable reached statistical significance by 8 years postcolposuspension. The

results add support to the view that there is an association between colposuspension and the development of symptomatic POP (requiring surgery).

KEY POINT: COMPLICATIONS OF RETROPUBIC REPAIRS

- Because retropubic suspensions are unable to correct central defect cystoceles, patients must be carefully examined preoperatively to exclude their presence and must be counselled if undergoing a colposuspension because of the high risk of needing further surgery in the long term. Particularly, those in whom a weakness of the posterior compartment is identified preoperatively and those with a past history of hysterectomy might be at increased risk.

COMPARISONS OF INCONTINENCE PROCEDURES

Retropubic Repair versus Needle Suspension and Anterior Repair

Three articles that reviewed the literature on incontinence procedures all found retropubic suspensions to be more effective than either needle suspensions or anterior colporrhaphies (Jarvis, 1994b; Black and Downs, 1996; Leach et al, 1997). Cure rates were approximately 85% for the retropubic suspensions compared with 50% to 70% for the needle suspensions and anterior colporrhaphies. Results were more durable for the retropubic suspensions and better if the procedure was primary.

Overall therefore there is now high-level evidence indicating that needle suspension procedures are as effective as anterior colporrhaphy but less effective than colposuspension even in the short term (evidence level 1). Long-term studies indicate lack of longevity even of the initial modest results; long-term complications remain a concern (evidence level 3) (Smith et al, 2009).

KEY POINT: RECOMMENDATIONS FROM THE INTERNATIONAL CONSULTATION ON INCONTINENCE COMMITTEE (SMITH ET AL, 2009)

- Endoscopic and nonendoscopic bladder neck needle suspension procedures, with and without bone anchors, are not recommended for the treatment of SUI (grade A recommendation).

Retropubic Repair versus Pubovaginal Sling

Most studies in the historical literature have not demonstrated a significant difference in cure rates between retropubic suspensions (usually a Burch procedure) and pubovaginal slings (Jarvis, 1994b; Black and Downs, 1996; Leach et al, 1997). However, often, selection bias exists in that the pubovaginal sling is usually reserved for patients with multiple prior failed incontinence procedures, with less prolapse, and the presence of presumed intrinsic sphincter deficiency (a fixed urethra with periurethral fibrosis) is often used in clinical practice as a contraindication to a retropubic suspension. In an interesting randomized study in patients with a prior failed incontinence procedure (anterior repair) but without a low-pressure urethra (i.e., MUCP <20 cm H₂O), **Enzelsberger's group (1996)** found no significant difference in cure (subjective or objective) at 32 to 48 months between the Burch procedure and the Lyodura sling. However, they noted significantly more postoperative voiding difficulty with the pubovaginal sling (13% vs. 3%) and more vaginal prolapse (enterocele or rectocele) with the Burch procedure (13% vs. 3%).

A high-quality multicenter randomized clinical trial in women with stress incontinence compared the Burch colposuspension with a pubovaginal sling, using autologous rectus fascia (**Aldo et al, 2007**). Women were eligible for the study if they had predominant symptoms associated with the condition, a positive stress test result, and urethral hypermobility. The primary outcomes were success in terms of overall urinary-incontinence measures, which required a negative pad test result, no urinary incontinence (as recorded in a 3-day diary), a negative cough and Valsalva stress test result, no self-reported symptoms, and no retreatment for the condition, and success in terms of specific measures of stress incontinence as well as an assessment of postoperative urgency incontinence, voiding dysfunction, and adverse events. A noteworthy aspect of the study was the careful approach to standardization (using the recommendations from the standardization committees of the International Continence Society) with regard to clinical terms, urodynamic nomenclature, and methods of evaluation of patients across all sites. Key elements of the two surgical procedures were standardized among all participating surgeons and included the use of preoperative antibiotics, skin-incision length, number and type of Burch sutures, fascial-sling length and width, and cystoscopic evaluation of the bladder. A criticism that can be leveled at the study is the choice of technique for the Burch colposuspension with very medial paraurethral sutures. The techniques utilized are demonstrated in **Figure 82-7**.

Because these procedures are frequently performed in conjunction with surgery for pelvic prolapse, abdominal and vaginal approaches for both pelvic prolapse repair and hysterectomy were permitted; however, surgeons were required to declare before randomization which concomitant procedures would be performed.

A total of 655 women were randomly assigned to study groups: 326 to undergo the sling procedure and 329 to undergo the Burch procedure; 520 women (79%) completed the outcome assessment. At 24 months, success rates were higher for women who underwent the sling procedure than for those who underwent the Burch procedure, for both the overall category of success (47% vs. 38%, $P = .01$) and the category specific to stress incontinence (66% vs. 49%, $P < .001$). There was no significant difference between the sling and Burch groups in the percentage of patients who had serious adverse events (13% and 10%, respectively; $P = .20$). However, more women who underwent the sling procedure had adverse events than in the Burch group, with 415 events among 206 women in the sling group as compared with 305 events among 156 women in the Burch group. This difference was primarily the result of urinary tract infections; 157 women in the sling group (48%) had 305 events and 105 women in the Burch group (32%) had 203 events. When urinary tract infections were excluded, although the rates of adverse events were similar in the two groups, there was more difficulty voiding.

The distribution of time to return to normal voiding differed significantly between the two groups ($P < .001$). Voiding dysfunction was more common in the sling group than in the Burch group (14% vs. 2%, $P < .001$). Consequently, surgical procedures to reduce voiding symptoms or improve urinary retention were performed exclusively in the sling group, in which 19 patients underwent 20 such procedures. (63% vs. 47%, $P < .001$). Treatment-satisfaction rates for the 480 patients who answered the satisfaction question at 24 months were significantly higher in the sling group than in the Burch group (86% vs. 78%, $P = .02$).

A further analysis of this study focused on sexual activity as assessed by the Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ-12) among those sexually active at baseline and 2 years after surgery (**Brubaker et al, 2009**). This report demonstrated that sexual function improves after successful surgery and does not differ between Burch and sling procedures.

Chai and colleagues (2009) reviewed complications in women undergoing Burch colposuspension versus autologous rectus fascial sling for SUI. These authors reviewed serious adverse events in the Stress Incontinence Surgical Treatment Efficacy Trial (SISTER). The conclusion reached was that concomitant surgery and continence procedures increased the risk of complications. Sling surgery was

Figure 82-7. In the Burch colposuspension (A), sutures are placed in the anterior vaginal wall at the level of the bladder neck and proximal urethra and sutured to the iliopectineal ligament. In the autologous sling procedure (B), a strip of rectus fascia is harvested and permanent sutures placed at both ends. The sling is positioned beneath the urethra via a vaginal incision. The two ends of the sling are then secured to the anterior abdominal wall, either together or to the rectus fascia. (Modified from Aldo ME, Richter HE, Brubaker L, et al. Burch colposuspension versus fascial sling to reduce urinary stress incontinence. *N Engl J Med* 2007;356:2143–55.)

associated with a higher risk of cystitis within the first 6 weeks postoperatively, and intermittent self-catheterization increased the risk of cystitis in this group. Complications were associated with surgical factors and not with patient-related factors. The authors concluded that blood loss and operative time were significantly associated with adverse events. Intermittent self-catheterization increased the cystitis rate by 17% and 23% in the Burch and sling groups, respectively.

Kraus and colleagues (2011) reported on changes in urodynamic measures 2 years after Burch colposuspension or autologous sling surgery in a report from this large study (SISTER). They noted that 655 women underwent standard urodynamic studies before and 2 years after Burch or sling surgery. The conclusion reached was that the Burch colposuspension autologous fascial sling procedure was associated with similar decreases in noninstrumental flow rates and that slings were associated with great increase in the detrusor pressure at maximum flow and bladder outlet obstruction index. They concluded that these changes suggested that both procedures were effective in part because of increasing outlet resistance; it was suggested that sling procedures might be more obstructive based on the urodynamic parameters measured.

Richter and colleagues (2012) reviewed patient-related factors associated with long-term urinary continence after Burch colposuspension and pubovaginal fascial sling surgery in a long-term follow-up of SISTER. The follow-up of patients in this study was up to 7 years after surgery. The authors concluded that urinary continence rates decreased during a period of 2 to 7 years postoperatively

from 43% to 13% in the Burch group and from 53% to 27% in the sling group. The baseline factors included in the first multivariate model were age, prior SUI surgery, menopausal state, urge index, assigned surgery, and recruiting site. All of these were independently associated with increased risk of incontinence. In the final multivariate model, included baseline and postoperative factors were Burch surgery, baseline variables of prior urinary incontinence surgery, menopausal state, and postoperative urge index. All of these were significantly associated with a greater risk of recurrent urinary incontinence. The authors concluded that preoperative and postoperative urgency incontinence symptoms, Burch urethropexy, prior SUI surgery, and menopausal status were negatively associated with long-term continence rates. More effective treatment of urgency urinary incontinence in patients who undergo SUI surgery may improve long-term overall continence rates. They concluded that in women followed for a minimum of 5 years after Burch colposuspension or pubovaginal fascial sling, prior SUI surgery, being menopausal without hormone replacement therapy, having undergone a Burch procedure, and increased postoperative urgency incontinence symptoms were significantly associated with long-term incontinence. The final conclusion was that knowledge of risk factors for surgical failure can be used to better inform patients of the likelihood of long-term continence or decreased continence rates to be experienced as a result of the surgery. The suggestion put forward is that overall continence status may be improved by proactive preoperative and postoperative assessment and effective treatment of urgency incontinence.

KEY POINT: RETROPUBIC REPAIR VERSUS PUBOVAGINAL SLING

- It can be reliably concluded that in specialist centers working in a standardized fashion, the autologous fascial sling results in a higher rate of successful treatment of stress incontinence but also greater morbidity than the Burch colposuspension.

Burch Colposuspension versus Marshall-Marchetti-Krantz Procedure versus Paravaginal Repair

In general, comparisons between the MMK and the Burch procedures have yielded similar results. [Jarvis, in his meta-analysis of the literature \(1994b\)](#), noted that overall continence rates were 89.6% and 83.9% for the MMK and the Burch procedures, respectively. When he looked at the effect of prior incontinence surgery, the continence rates were 92.1% and 94% when there was no prior surgery and 84.5% and 84% when there was a history of prior incontinence surgery for the MMK and Burch procedures, respectively. Similarly, [Black and Downs \(1996\)](#), in reviewing five studies (one randomized) that directly compared the MMK procedure with the Burch procedure, found that there was no significant difference in cure rates between the two procedures, although the Burch procedure yielded better results in general. However, they pointed out that overall the studies were of poor quality with small sample sizes.

Two randomized studies that assessed urethral sphincteric function by urethral pressure profilometry had conflicting results. [Quadri's group \(1999\)](#) compared the MMK procedure with the Burch procedure in women with a hypermobile, low-pressure urethra (MUCP <20 cm H₂O) and noted significantly higher subjective and objective 1-year cure rates with the MMK procedure. They used urethroscopy to facilitate MMK suture placement. On the other hand, [Colombo's group \(1994\)](#) excluded women with a low-pressure urethra (MUCP <30 cm H₂O) and performed a cystotomy to facilitate MMK suture placement. With 2- to 7-year follow-up (mean, 3 years), they noted higher subjective and objective cure rates with the Burch procedure, although these were not statistically significant. In addition, significantly more MMK patients had persistent postoperative voiding difficulties (28% vs. 8%).

The literature on the paravaginal repair is sparse. The only randomized study that compared the Burch procedure with a paravaginal repair found significantly greater subjective and objective cure with the Burch procedure ([Colombo et al, 1996a](#)). Until large, randomized studies with prolonged follow-up are available, the issue of which is the best procedure will remain unresolved.

Tension-Free Vaginal Tape Procedure versus Colposuspension

Since its introduction in 1996 by Ulmsten, the TVT procedure has gained widespread acceptance for treatment of SUI, given its low morbidity, short-term success rates, and ability to be performed as an outpatient procedure with use of a local or regional anesthetic ([Ulmsten et al, 1996](#)). The 7-year objective and subjective success rate for TVT is 81% ([Nilsson et al, 2004](#)). In a more recent review of this series, 77% of the initial cohort of 90 women and 89% of those alive and capable of cooperating were assessed 11.5 years after the TVT operation. Ninety percent of the women had both negative stress test and negative pad test results and were considered to be objectively cured. Subjective cure by patients' global impression was found in 77%, 20% being improved, and only 3% regarded the operation as a failure. No late-onset adverse effects of the operation were found, and no case of tape erosion was seen ([Nilsson et al, 2008](#)).

There have been a number of well-designed, prospective, randomized trials comparing the Burch colposuspension (two open and two laparoscopic) with TVT.

[Liapis and coworkers \(2002\)](#) reported a prospective randomized comparative study of Burch colposuspension (n = 35) and TVT (n = 36). They concluded that at 2-year follow-up, the TVT and Burch procedures were equally effective with an objective pad test cure rate of 84% and 86%, respectively. TVT had a shorter operative time and entailed less postoperative pain with a faster return to normal activity.

[Ward and Hilton \(2004\)](#) published a 2-year follow-up of their landmark prospective randomized trial comparing TVT and OBC. At 2 years, 74% of the initial TVT and 69% of the open colposuspension patients completed the evaluation. The objective cure rates for the TVT (81%) and colposuspension (80%) were not significantly different. However, if the missing patients were evaluated by the last observation carried forward analysis, the cure rates would favor TVT (78% vs. 68%). It is interesting that the subjective cure rates differ from the objective rates dramatically, with only 43% and 37% reporting subjective cure of stress incontinence after TVT and colposuspension, respectively. At 2 years, the colposuspension group still had significantly lower scores on mental and emotional health. The incidences of enterocele and vault prolapse were higher in the colposuspension group, requiring significantly more prolapse surgery. Likewise, the number of patients still requiring intermittent catheterization was higher in the colposuspension group. The intra-operative complications were higher in the TVT group, whereas the postoperative complications were higher in the colposuspension group. The authors' conclusion at 2 years, because of patients lost to follow-up, was unchanged from their conclusion at 6 months, namely, that TVT may be better than, worse than, or the same as colposuspension.

A Cochrane review of open colposuspension examined a total of seven trials comparing TVT with open colposuspension ([Lapitan et al, 2005](#)), although the trial by Ward and Hilton noted earlier dominated the analysis. The review concluded that TVT and open colposuspension were equally effective but that TVT carried an increased risk of complications, particularly bladder perforation. A further cost-benefit analysis based on the Ward and Hilton study showed that TVT was a cost-effective alternative to colposuspension, largely based on shorter hospital stay and rapid return to work ([Manca et al, 2003](#)).

In a further report from the Ward and Hilton study, 98 of those who had TVT and 79 of those who had colposuspension returned for 5-year follow-up; 72 in the TVT group and 49 in the colposuspension group had full subjective and objective data ([Ward et al, 2008](#)). The primary outcome in this analysis was a negative 1-hour pad test result, and this was not significantly different between the two groups: 58 of 72 (81%) women in the TVT group and 44 of 49 (90%) in the colposuspension group ($P = .021$, Fisher's exact test) at 5 years. Significantly, more women in the colposuspension group (11 [7.5%]) underwent surgery for prolapse during the follow-up period than those in the TVT group (3 [1.8%]). Tape-related complications were seen in 6 women. In the first year, one tape was divided for obstructed voiding; there was one suprapubic extrusion and one vaginal erosion. Two further vaginal erosions were detected at 5-year follow-up, and in addition, 1 woman was found to have tape within the bladder at cystoscopy after complaining of overactive bladder symptoms. There were no reported suture-related complications in the colposuspension group.

[Persson and coworkers \(2002\)](#) were one of the first groups to compare TVT and laparoscopic Burch colposuspension. At 1-year follow-up, there was no difference between objective and subjective cure rates. [Valpas and associates \(2004\)](#) conducted a prospective randomized trial comparing TVT and laparoscopic mesh colposuspension at 1-year follow-up. The objective cure rate (negative stress test result, 86% vs. 57%), satisfaction, and quality of life were statistically better for the TVT group.

[Paraiso and colleagues \(2004\)](#) prospectively randomized 72 patients into laparoscopic Burch colposuspension and TVT at a mean follow-up of 20 months, but only 17 and 16 patients were

KEY POINTS: LONG-TERM EFFICACY OF TENSION-FREE VAGINAL TAPE AND COLPOSUSPENSION

- The effect of both procedures on cure of incontinence and improvement in quality of life appears from this follow-up of a portion of the originally treated patients to be maintained in the long term out to 5 years (Ward et al, 2008). Eight-one percent of the women who had undergone TVT and 90% who had undergone colposuspension regarded themselves as satisfied or very satisfied with the results of their surgery at 5 years.
- The key messages in terms of adverse events are that vault and posterior vaginal wall prolapse are seen more commonly after colposuspension and that late tape erosion may occur several years after surgery.

available in the laparoscopic and TVT groups, respectively. Whereas objective and subjective cure rates were significantly higher in the TVT group, satisfaction of patients was equal in each group, and no difference was reported in voiding dysfunction, urgency, or symptomatic pelvic prolapse. All these laparoscopic studies require longer follow-up with greater power to demonstrate a persistent difference between TVT and Burch colposuspension.

A meta-analysis of the literature has been reported by Novara and colleagues wherein they combined the results of open and laparoscopic colposuspension (Novara et al, 2007). To date, nine RCTs have compared TVT with Burch colposuspension as primary

treatment for SUI (Liapis et al, 2002; Persson et al, 2002; Ward and Hilton, 2002; Ustün et al, 2003; Paraíso et al, 2004; Valpas et al, 2004; Ward et al, 2004; Bai et al, 2005; El-Barky et al, 2005). A further study compared Suprapubic Arc Sling (SPARC; American Medical Systems, Minnetonka, MN) with laparoscopic Burch colposuspension (Foote et al, 2006). TVT was followed by significantly higher continence rates compared with Burch colposuspension, considering success rates evaluated according to any definition of continence (OR 0.58, 95% CI OR 0.42 to 0.79, $P = .0007$), presence of negative stress test result (OR 0.38, 95% CI OR 0.25 to 0.57, $P < .0001$), and negative pad test result (OR 0.59, 95% CI OR 0.41 to 0.85, $P = .005$).

A study has contrasted direct health care costs of treatment for SUI in Sweden with four different procedures: (1) OBC; (2) laparoscopic colposuspension with sutures (LCS); (3) laparoscopic colposuspension with mesh and staples (LCM), and (4) TVT (Ankardal et al, 2007). A model was constructed representing a hospital with standardized surgical equipment, staff, and average unit costs in 2003 euros. The time used for anesthesia and surgery was calculated. Clinical data were collected from three different sources: a multicenter, randomized, prospective study comparing OBC with LCM with 1-year follow-up; a three-armed prospective study in which women were randomized to OBC, LCM, or LCS with 1-year follow-up; and a descriptive study reporting results of TVT with 5-year follow-up. Data collected from the studies and hospital cost data were put into the model to create the different cost elements. The total cost per individual showed a lower cost for TVT compared with the other alternatives. The direct costs for TVT were only 56% of the costs for OBC ($P < .001$) and 59% of the costs for LCS

KEY POINTS: RETROPUBIC SUSPENSION SURGERY FOR INCONTINENCE

- Anti-incontinence surgery does not necessarily work by restoring the same mechanism of continence that was present before the onset of incontinence. It works by a compensatory approach.
- The surgeon's preference, coexisting problems, and anatomic features of the patient and her general health condition influence the choice of procedure.
- There is lack of a clear consensus as to which surgical procedure for stress incontinence is most effective, but contemporary practice is shifting to the "loose" urethral sling being the most widely used and having largely replaced the colposuspension.
- A number of variables may influence surgical outcome: age, postoperative activity, medical comorbidity, obesity, duration of symptoms, coexistence of detrusor overactivity, prior surgery, and intrinsic sphincter deficiency.
- There is no consensus on how to differentiate the relative contributions of hypermobility and sphincteric weakness.
- There remains no consensus on how to assess the outcomes of surgery, but this requires careful assessment with adequate follow-up and use of simple objective measures as well as taking particular account of patient-perceived outcomes.
- During short-term follow-up, vaginal and open retropubic suspension procedures have similar success rates. With longer follow-up (and with the exception of the pubovaginal sling), patients who have retropubic procedures fare better.
- With the MMK procedure, placement of sutures through the pubic symphysis incurs the risk of osteitis pubis in 0.9% to 3.2% of patients.
- Burch colposuspension is as effective as any other procedure in primary or secondary surgery at curing SUI, with proven long-term success. Thus it should be regarded as the *standard* open retropubic procedure for incontinence.
- Abdominal paravaginal repair is less effective than other forms of colposuspension.
- As with any major abdominal or pelvic surgical procedure, intraoperative and perioperative complications that may occur after a retropubic suspension include bleeding, injury to genitourinary organs (bladder, urethra, ureter), pulmonary atelectasis and infection, wound infection or dehiscence, abscess formation, and venous thrombosis or embolism. Other common complications more specific to retropubic suspension procedures include postoperative voiding difficulty, detrusor overactivity, and vaginal prolapse.
- The risk of temporary urinary retention lasting more than 4 weeks postoperatively is 5% for all retropubic suspensions. The risk of permanent retention is estimated to be less than 5%. These risks are not significantly different from those of needle suspensions or pubovaginal slings.
- All patients should be counseled before surgery about the potential need for intermittent self-catheterization.
- Because retropubic suspensions are unable to correct central defect cystoceles, patients must be carefully examined preoperatively to exclude their presence. The Burch procedure, because of lateral vaginal elevation, may aggravate posterior vaginal wall weakness, predisposing to enterocele.
- Retropubic suspensions are more effective than either needle suspensions or anterior colporrhaphies.
- Laparoscopic colposuspension is not recommended as a routine surgical procedure and when performed should be carried out only by a surgeon skilled in laparoscopic surgery.
- Most studies in the literature have not demonstrated a significant difference in cure rates between retropubic suspensions (usually a Burch procedure) and pubovaginal slings.
- Comparisons between the MMK procedure and the Burch procedure have yielded similar results in general.
- The literature on the paravaginal repair is sparse. The only randomized study that compared the Burch procedure with a paravaginal repair found significantly greater subjective and objective cure rates with the Burch procedure.
- At this time, the TVT procedure appears to be at least equivalent to the Burch colposuspension, and in general is probably better.

($P < .001$). It was concluded that with use of a model and in comparing health care costs for surgical treatment of female SUI in Sweden, the TVT procedure generated a lower direct cost than both open and laparoscopic colposuspension.

The shift in practice pattern away from Burch colposuspension for the treatment of SUI to mid-urethral slings as the primary treatment of SUI shows one of the difficulties in conducting surgical RCTs, especially when the field has changed as quickly as it has in recent years in the treatment of urinary incontinence. A recent survey of urogynecology fellows found that the average third-year fellow had performed 257 mid-urethral sling procedures and only 13 Burch procedures (LeBrun et al, 2008). It would be interesting to determine if surgeon's experience with Burch colposuspension is correlated with outcomes. Indeed, the outcomes reported in the existing literature base are likely to be very different from those seen in many clinicians' clinical practices, where this has become a rare operation and where many have had very limited experience of carrying out the procedure during their training over the last decade.

A 10-year follow-up study reached the conclusion that TVT is more cost-effective than Burch colposuspension in the treatment of female SUI (Laudano et al, 2013). The conclusion reached was that both the cost and the effectiveness of TVT affected the cost-effectiveness analysis. The major criticism of any such study is that it does not take account of potential complications, which are never adequately considered in any such study, bearing in mind the potential publication bias in the literature toward best practice from specialized centers and the concern that the complications seen in real-life practice may not be reflected in the published literature. Nevertheless, this is a well-conducted study and does provide clear evidence that TVT is a cost-effective alternative.

At this time, TVT appears to be an equivalent operation to the open or laparoscopic Burch colposuspension. Although a meta-analysis (Novara et al, 2007) suggested superiority of TVT, this analysis combined open and laparoscopic procedures and studies of variable quality. It is likely that single high-quality comparative studies have greater reliability (Ward and Hilton, 2004, 2008). TVT or transobturator tape (TOT) procedures have now largely supplanted colposuspension in contemporary practice. An open colposuspension should still be considered as a surgical option in patients undergoing open surgery and still has a role when

there is associated prolapse. Laparoscopic colposuspension has been shown in the short term to have some advantages over open colposuspension in experienced hands, but as a procedure has largely been supplanted by TVT or TOT in contemporary practice. Having noted the evidence for this, there is currently considerable concern over the potential risk of "exposure" of synthetic slings noted to occur in up to 5% in the Ward and Hilton study (Jones et al, 2010). It is essential to counsel patients accordingly, and there may be a change in practice toward autologous sling material and colposuspension in the future.

ACKNOWLEDGMENT

I would like to thank Richard Turner-Warwick for allowing in this chapter the use of figures from our book.

Surgical Anatomy of the Pelvic Floor

Site-Specific Defects by Compartment (Identification)

Preparing the Patient for Prolapse Surgery

Biologic and Synthetic Materials in Prolapse Surgery

Surgical Management of Pelvic Organ Prolapse

Surgical treatment of pelvic organ prolapse (POP) is one of the most challenging problems faced by pelvic floor surgeons. The cause is usually multifactorial; the clinical presentation and impact on the patient's quality of life (QoL) may vary considerably. Surgical correction is aimed at addressing defects in the supporting structures, which requires a comprehensive understanding of pelvic floor anatomy and function. Pelvic floor defects have been traditionally named for the prolapsing visceral organs; however, it is important to conceptualize that these disorders have less to do with the prolapsing organs and more to do with compartmental defects in the supportive tissues. Just as any hernia represents a defect in the fascia, POP represents herniations or descensus of the bladder, rectum, bowel, uterus, and urethra through defects in the pelvic floor connective tissues. Procedures must be tailored to the patient's unique presenting factors, such as comorbidities and concomitant pathology of the pelvic floor, as well as patient goals and expectations in surgical restoration of pelvic organ support. The aim of this chapter is to provide a practical overview of the surgical anatomy and discuss the vaginal and abdominal (open and laparoscopic or robotic) techniques for the treatment of POP.
